received on 20 November 2008

**Abstract.** In 2002–2008, occurrence of the European ground squirrel was recorded at or reported from 45 sites in the Czech Republic. However, only 35 sites were verified to host ground squirrel colonies in 2008. Most of the colonies (91%) were found in some kind of artificial habitat with high anthropogenic influence. Only (9%) of the European ground squirrel colonies occurred in natural steppe habitats. Although three sites (9%) were recorded at altitudes above 550 m, majority of the sites (60%) were situated below 300 m a. s. l. In most (54%) of the colonies, the estimated abundance was 50 individuals or less. Only one third of the colonies hosted 100 individuals or more. Considering the fact that 7 sites were abandoned in the period 2002–2008, it can be concluded that the decline of the European ground squirrel in the Czech Republic continues.

**Key words.** European ground squirrel, *Spermophilus citellus*, distribution, habitat.

### INTRODUCTION

The European ground squirrel, *Spermophilus citellus* (Linnaeus, 1766), currently ranks among the most threatened mammal species of the Czech fauna. Listed as a critically endangered species, it is protected by the Act no. 114/1992 Coll. on Nature Conservation and Landscape Protection. An action plan aimed at long-term preservation of the European ground squirrel as a wild living species in the Czech Republic was adopted by the Ministry of Environment in 2008 (MATĚJŮ et al. 2007).

Historical data on *S. citellus* distribution in the area of the present Czech Republic are very scarce. Apparently, their number and quality has gradually increased with population decline of the species. Only fragmentary notes of regional character were available till the half of the 20th century, e.g. KAFKA (1892), WEISBAUER (1894), PRAŽÁK (1896), JACOBI (1902) and ZÁLESKÝ (1924). Distribution range of the *S. citellus* in Czechoslovakia was described first in the early

1950s, when the species probably reached its peak numbers in the country and became an important pest (GRULICH 1960). Due to the changes in agricultural practices causing destruction of small landscape patches, the *S. citellus* has declined since the 1960s (ANDĚRA & ČERVENÝ 2004). In the Czech Republic, this trend was recorded by two questionnaire surveys: one organised by the Department of Zoology, Faculty of Science, Charles University in Prague in 1972 and another one managed by the Department of Zoology, National Museum in 1991. Using this data, occurrence of the *S. citellus* was mapped in the mid 1990s by ANDĚRA & HANZAL (1995). A complete overview of the *S. citellus* distribution in the Czech Republic in 2000 and 2001, with respect to the forthcoming selection of Natura 2000 sites, was published by CEPÁKOVÁ & HULOVÁ (2002). All available records of *S. citellus* occurrence (including historical data) in the Czech Republic were listed by ANDĚRA & ČERVENÝ (2004).

The aim of this study, carried out in 2002–2008 as a part of preparation and implementation of the *S. citellus* action plan, is to present new data on the species' distribution in the country and to compare them with previous knowledge.

## MATERIAL AND METHODS

The study is based mainly on data collected by the authors during mapping of *S. citellus* occurrence and regular monitoring of their abundance in the period 2002–2008. Moreover, data collected by regional offices of the Agency for Nature Conservation and Landscape Protection of the Czech Republic (ANCLP CR) and data from other regional contributors are included. A database of records including vector GIS maps of the sites is deposited at the ANCLP CR, Prague.

Order of the sites in the list below follows the numeral code of  $11.2 \times 12$  km squares of the Central-European KFME mapping grid (EHRENDORFER & HAMANN 1965, SLAVÍK 1971). The following data are given for each site: 1 – municipality name (in bold), 2 – district name (in brackets), 3 – more detailed description of the site, 4 – altitude and 5 – WGS coordinates of the site. In each site, a list of records of the species in particular years is given, including negative records (neg.). The records include: 6 – date of observation, 7 – observation details (where available, the number of individuals observed or burrow entrances found is mentioned, and/or an estimate of the total abundance is given – see below; neg. = negative record, i. e. neither individuals nor burrow entrances recorded), 8 – name of observer(s), 9 – reference (where appropriate). Note: All available data were used in the list below, despite the fact that inconsistent information on the status of the colony in the given year can be found in some sites.

Municipality names follow PRUNER & MÍKA (1996). Altitude values were obtained as an intersection of a centroid of the polygon defining the area of an *S. citellus* colony with a vector surface contour map using the ArcMap™ 9.2 software (ESRI Inc.).

In the sites visited by the authors of this paper, abundance of local *S. citellus* colonies (populations) was estimated. Regarding the lack of a standard method for estimating *S. citellus* abundance (GRULICH 1960, CEPÁKOVÁ & HULOVÁ 2002, MATĚJŮ et al. 2007), the estimation was based on personal experience of the authors and the following data: (a) number of individuals observed during all visits in the particular year; (b) area of the colony (i.e. total size of the area where burrow entrances were found). In the field, borders of each colony were marked in an air photo with 0.2 m resolution and after digitalisation of the data, colony area was calculated using the ArcMap software. In vineyards, orchards and gardens, not allowing an easy survey, only a rough identification of the borders of the *S. citellus* colonies was made; (c) comparison of the estimated abundance of the particular colony with the results obtained during visits of other sites in the same year; (d) comparison of the estimated abundance of the particular colony with relevant observations from previous years (if available). Considering consistence of the team of observers, possible subjective errors should be minimized, allowing comparison of the obtained data.

Population density values (number of individuals per hectare) were calculated using the estimated abundance of the colony and its area. For the analysis of "land cover" types, the sites were classified using the

following categories: a) airfield or airport, b) campsite or sport area, c) meadow or pasture, d) vineyard, orchard or garden and e) “natural” habitat – steppe.

## RESULTS – LIST OF SITES

**5356: 1. Hodkovice nad Mohelkou** (Liberec dist.), airfield, 445 m a. s. l.; N 50° 39' 11.5" E 15° 04' 35.4". 2 May 2003: estimated abundance max. 10 inds., E. CEPÁKOVÁ; September 2004: neg., M. #### Sites with reported occurrence (not visited by the authors):

**7066: 43. Hustopeče u Brna** (Brno-venkov dist.), gardens, vineyards and fields, 230 m a. s. l.  
19 June 2007: up to 5 inds. observed, occurrence reported for approximately the last 10 years, A. KONEČNÝ (ad verb.).

**7162: 44. Konice** (Znojmo dist.), vineyards at E periphery of the village, 290 m a. s. l. July 2008: 1 ind. observed L. KRATOCHVÍL, occurrence also reported by landowner Mr. JELÍNEK (VALÁŠEK ad verb.).

**7263: 45. Jaroslavice** (Znojmo dist.), slopes of the Kočičí vrch hill, vineyards and meadows, 246 m a. s. l. 17 July 2007: 1 ind. observed P. ČERVENKA (M. ANDĚRA ad verb.)

#### ASSESSMENT OF DISTRIBUTION

In total, occurrence of the *S. citellus* was recorded at or reported from 45 sites (32 squares of the KFME mapping grid) in the Czech Republic in 2002–2008 (Table 1, Fig. 1). Of them, only 35 sites (29 squares) were proved by the authors to host *S. citellus* colonies in 2008 (as per 1 September). *S. citellus* colonies probably vanished from 7 sites (no. 9, 10, 11, 17, 20, 23 and 27) during the period 2002–2008 and the status of 3 sites has remained uncertain. On the other hand, 14 previously unknown sites or non verified sites were visited and confirmed to host *S. citellus* colonies in the study period (new sites no. 12, 17, 31, 33, 34, 35, 36, 37, 41, 42; newly verified no. 8, 23, 27, 28).

The current distribution range of the *S. citellus* in the country includes south-Moravian lowlands (Brno, Znojmo, Břeclav, Hodonín, Vyškov and Blansko districts) with 18 sites, central Bohemia (Praha, Mladá Boleslav, Kladno, Příbram and Beroun dist.) and neighbouring parts of northern Bohemia (Liberec, Litoměřice and Louny dist.) with 12 sites. Only two sites are situated in north-western Bohemia (Karlovy Vary dist.), one in south-western Bohemia (Strakonice dist.) and two in southern Bohemia (Jindřichův Hradec dist.). The fragmentary pattern of the *S. citellus* distribution is highly apparent and the migration of individuals between colonies is perhaps possible only among some south-Moravian sites and two sites in the České středohoří region (nos. 2, 3). In the other cases, migration is probably impossible as distances between the sites usually reach tens of kilometres.

\*total size of colony and even its existence are uncertain

More than a half (19, 54.3%) of the *S. citellus* colonies hosted 50 individuals or less (Table 2). Only 12 colonies (34.3%) numbered 100 individuals or more. In the smallest colonies (sites no. 16 and 25), the estimated *S. citellus* abundance was only 5 and 8 individuals, respectively. The presence of a single individual was documented in the extreme case of the site no. 42. In the largest colonies (sites no. 13 and 24), the estimated abundance reached 650 individuals. The total size of the *S. citellus* population in the Czech Republic in 2008 was estimated at approx. 3600 individuals (Table 2).

Mean population density in the colonies, based on the estimated abundance, was 15.1 ind./ha (median 10.9; range 2.1–58.7; n=35). The lowest density (about 2 ind./ha) was recorded at three sites (no. 5, 12 and 34) with different land cover types: natural habitat – steppe, airfield or airport, and vineyard, orchard or garden, respectively. The highest density (58.7 ind./ha) was found at the airfield site no. 19. The second highest density (48.4 ind./ha) was recorded in a campsite area (site no. 29), which is situated at the highest elevation among the currently known Czech localities. Concerning land cover type, the lowest population densities were found in steppe habitats (mean = 6.6 ind./ha, range 2.2–10.1 ind./ha). Very similar values were recorded at airfields or airports (mean = 12.1 ind./ha, range 2.1–58.7 ind./ha), and meadows or pastures (mean = 18.3 ind./ha, range 6.1–35.8 ind./ha). Campsites and sport areas showed the highest *S. citellus* population densities (mean = 27.8 ind./ha, range 13.9–48.4 ind./ha). Concerning vineyards, orchards and gardens, we were unable to identify borders of the colonies precisely, however, it

is not clear whether the *S. citellus* occurrence in this land cover type really has a character of colony settlement, so we did not calculate the densities for this land cover type.

Altitudinal distribution of the species in the Czech Republic is shown in Fig. 2. The mean altitude of sites with *S. citellus* occurrence was 317 m a. s. l. (range 155–648 m a. s. l., median 260 m a. s. l.), with 60% of the sites situated below 300 m a. s. l.

European ground squirrels in the Czech Republic were often found in airfields and airports (see Fig. 3), which host 43% of the known colonies and more than 70% of the total Czech *S. citellus* population (individuals). This “land use/land cover” type also hosts the largest (area of colony) and most numerous *S. citellus* colonies. Concerning the number of *S. citellus* colonies, the second largest number was found in the “vineyard, orchard or garden” type, followed by “meadows or pastures” and “campsites or sport areas” (Fig. 3). The lowest number of *S. citellus* colonies was found in “natural”, steppe habitats (Fig. 3).

## DISCUSSION

In the study period, occurrence of *S. citellus* was recorded at 35 sites in the Czech Republic, i.e. nine more compared to those reported by CEPÁKOVÁ & HULOVÁ (2002). Four *S. citellus* colonies (no. 9, 10, 11 and 20) of those verified by CEPÁKOVÁ & HULOVÁ (l. c.) in 2000–2001 became extinct. In addition, disappearance of three other colonies which were either unknown (no. 17), not verified (no. 23) or erroneously considered as extinct (no. 27) in the previous study (CEPÁ-

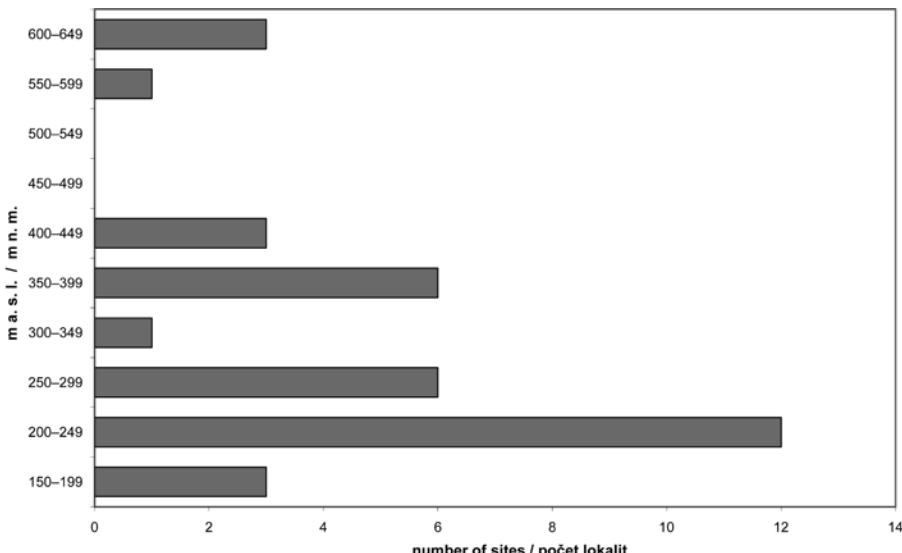

Fig. 2. Altitudinal distribution of the *S. citellus* in the Czech Republic in 2008 (only sites verified as per 1 September 2008 were included, n=35).

Obr. 2. Hypsometrické rozšíření sysla obecného v ČR v roce 2008 (zahrnutý jsou pouze lokality ověřené k 1. září 2008, n=35).

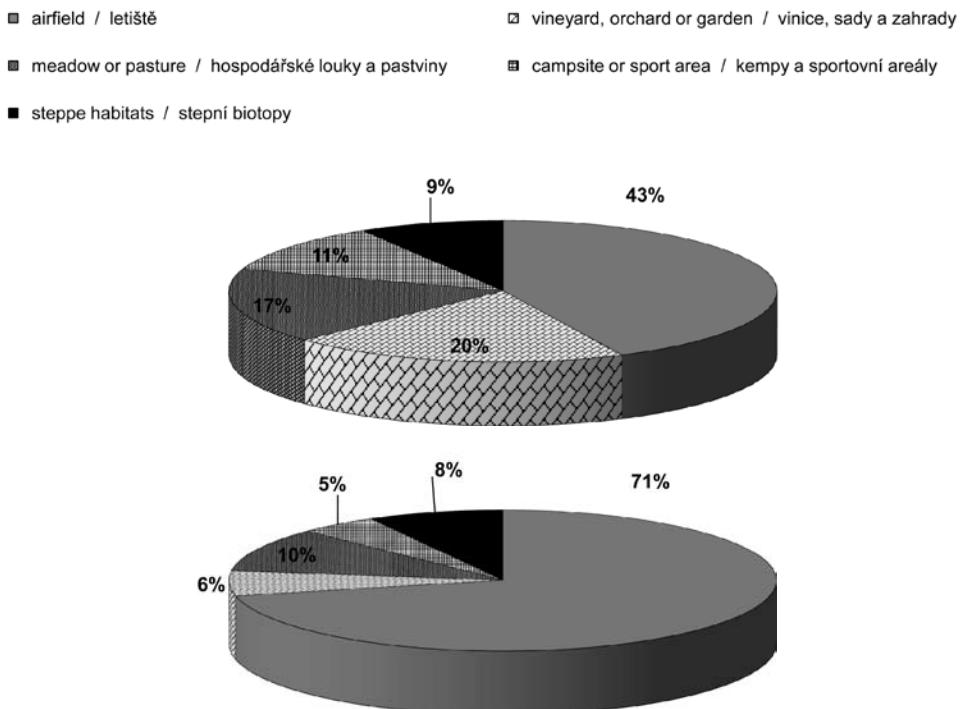

Fig. 3. Top – proportion of *S. citellus* colonies in different land cover types (only sites verified as per 1 September 2008 were included, n=35); below – proportion of numbers of *S. citellus* individuals in different land cover types (n=3599).

Obr. 3. Nahoře – zastoupení lokalit sysla v jednotlivých typech "land-cover" (zahrnutý jsou pouze lokality ověřené k 1. září 2008, n=35); dole – zastoupení počtu jedinců v jednotlivých typech "land-cover" (n=3599).

KOVÁ & HULOVÁ l. c.) was observed during the period 2002–2008. Presence of *S. citellus* was newly discovered or verified at 14 sites; one of the colonies was probably established as a result of the reintroduction action (MATĚJŮ et al. 2007). It should be noticed that the newly recorded sites are not newly established colonies but they have been only recently discovered.

In the Czech Republic, the *S. citellus* reaches the western and northern limits of its distribution range (sites no. 7+8 and 1, respectively, being the extremes) – the situation is the same as described by CEPÁKOVÁ & HULOVÁ (l. c.). This fact somewhat complicates the comparison of *S. citellus* distribution in the country with the rest of the species' range, since the present situation may be influenced by natural oscillations (ANDĚRA & ČERVENÝ 2004), which are generally most visible on the periphery of the distribution range (LOMOLINO et al. 2005).

The pattern of *S. citellus* distribution in Austria, Slovakia and Hungary is quite similar, however, the sites (colonies) in these countries are more numerous, more populated and also less isolated (AMBROS 2000 and pers. comm.; VACZI ad verb., ENZINGER et al. 2008). The esti-

mated number of *S. citellus* colonies in Hungary is between 200 and 300 (O. VÁCZI ad verb.). About 250 colonies are present in Lower Austria (ENZINGER et al. 2008) and approximately 100 colonies were known in Slovakia in the period 1997–1999 (AMBROS 2000). However, *S. citellus* populations in these countries are also closely related to anthropogenic habitats such as fallow land, vineyards, field margins, golf courses, public baths and industrial sites (ENZINGER et al. 2008). Comparison of our results with the situation in Bulgaria and Romania, where the occurrence of *S. citellus* still has a natural character, is difficult due to limited data available and due to different climatic conditions in these countries.

In comparison with older data (e.g. GRULICH 1960, Fig. 4), it is evident that the current *S. citellus* distribution has a relict character, with only few existing sites as remains of the continuous distribution range in the early 1950s (Fig. 4). The dramatic decline of the species was caused by intensification of agricultural practices in the 1960s, i.e. alteration of meadows and pastures into fields and absence of regular mowing in the remaining grasslands, resulting in habitat loss and fragmentation (CEPÁKOVÁ & HULOVÁ 2002, ANDĚRA & ČERVENÝ 2004, MATĚJŮ et. al 2007). At present, *S. citellus* colonies are restricted to the grasslands regularly managed by man – air-fields, sport areas, gardens, vineyards and orchards. Preference of these highly anthropogenic habitats suggests high dependence of the *S. citellus* population on human activities.

Population densities of the *S. citellus* (number of individuals per hectare) significantly differ between the sites and show marked interseasonal fluctuations (HOFFMANN et al. 2003, MRLÍ-

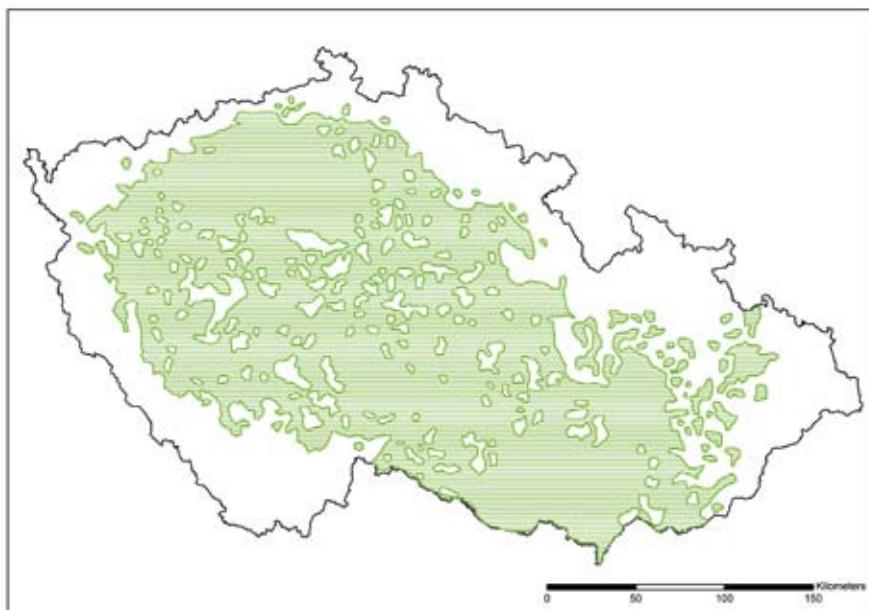

Fig. 4. Distribution of the *S. citellus* in the Czech Republic during the period 1949–1953. Redrawn from GRULICH (1960).

Obr. 4. Rozšíření sysla obecného na území České republiky v letech 1949 až 1953. Upraveno podle GRULICHA (1960).

KOVÁ 1999, KOSNAR 1979, RUŽIĆ 1978). The lowest densities recorded in the Czech Republic are somewhat lower than those usually reported from other parts of the distribution range, e.g. 6.0–15.6 inds./ha, Mimoň, Czech Rep. (MRLIKOVÁ 1999) and results of this study compared to 4.0–88.0 inds./ha, Neradin, Krušedol, Banatska Palanka, Serbia (ČIROVIC et al. 2008); 18.0–48.0 inds./ha, S Banat, Serbia (RUŽIĆ 1978); or 6.3–61.0 inds./ha (only adults), Langenzersdorf, Austria (HOFFMANN et al. 2003). This may be a result of the location of Czech populations on the periphery of the species' distribution range – i.e. in the area with less-favourable environmental conditions (LOMOLINO et al. 2005).

SAUER (1976) and TURRINI et al. (2008) report high densities of *Spermophilus beldingi* and *S. citellus* populations occupying highly productive habitats (e.g. alfalfa fields). This suggests that the *S. citellus* density may be related to the productivity of the habitat. Our data could support this hypothesis. In steppe habitats which are usually mowed and pastured only extensively, the availability of fresh food decreases during the season due to accumulation of the dry old grass. On the other hand, in the land cover types where the grass is regularly mowed or pastured (meadows or pastures, airfields or airports, camp sites or sport areas), a sufficient amount of fresh food (i.e. newly grown grass) is ensured throughout the season (BIBIKOV 1996). Frequent provision of additional food was observed in campsites and sport areas, which may significantly increase the “habitat productivity” and thus enable the *S. citellus* to live in higher densities. Future studies should focus on the comparison of population densities in *S. citellus* colonies occurring in habitats with different primary productivity.

Altitudinal distribution of the current *S. citellus* sites corresponds with the results of CEPÁKOVÁ & HULOVÁ (l.c.) as well as with the data from Austria, where *S. citellus* colonies were recorded at elevations below 600 m a. s. l. (SPITZENBERGER 2001). Considering the previous studies by GRULICH (1960) and BÁRTA (1992) who reported frequent occurrence of the *S. citellus* at medium elevations up to 700 and 800 m a. s. l., respectively, survival of the species seems to be better at lower elevations where most of the current colonies were preserved.

The above data indicate two main facts. First, our knowledge of *S. citellus* distribution in the Czech Republic has improved and it is more accurate. Second and more important, it is apparent that the *S. citellus* population in the Czech Republic is highly fragmented and the number of colonies (sites) is still decreasing, as the newly recorded sites are not newly established colonies but they have been only recently discovered. These populations are relicts of the past distribution and are very sensitive to any disturbance. Therefore, we consider adoption of the species action plan as fully justified and hope that this study will contribute to its successful implementation.

## SOUHRN

Cílem předložené práce je sumarizace poznatků o rozšíření sysla obecného v ČR v letech 2002–2008 a porovnání aktuálního stavu se staršími údaji. Výskyt sysla byl mapován na území celého státu především za pomoci pracovníků AOPK ČR v rámci přípravy a realizace jeho záchranného programu. Na všech lokalitách s výskytem sysla bylo stabilním týmem pozorovatelů opakovaně (obvykle v dubnu a červenci) prováděno vizuální sčítání aktivních jedinců a případně sčítání vchodů do nor. Následně byl pro každou kolonii proveden odhad celkového počtu jedinců. Hranice plochy obývané kolonií byly vyznačeny v leteckých snímcích a digitalizovány v programu ESRI ArcGIS 9.2. Za období 2002 až 2008 se podařilo zjistit výskyt sysla na 45 lokalitách. V roce 2008 byl výskyt sysla potvrzen pouze na 35 z nich, 7 lokalit ve sledovaném období zaniklo a 3 zůstaly neověřeny. Většina současných lokalit (18) se nachází v nížinách jižní Moravy a přilehlých pahorkatinách, významnou oblastí jsou i střední Čechy a přilehlá část severních

Čech, kde bylo zjištěno 12 lokalit. Zbylých 5 lokalit se nachází v okresech Jindřichův Hradec, Karlovy Vary a Strakonice. Celková početnost sysla v ČR byla v červenci 2008 odhadnuta na 3600 jedinců. Jen třetina (12) všech kolonií však dosahovala početnosti 100 a více jedinců. Naopak na většině lokalit (19) byl počet syslů menší nebo roven 50. Červencová hustota osídlení v koloniích se pohybovala od 2,1 do 58,7 jedinců/ha (medián 10,9 jedinců/ha). Více než 90% kolonií se nacházelo v biotopech tvořených tzv. kulturními trávníky (polní letiště, vinice a zahrady, louky, sportoviště a rekreační areály), pouze 3 kolonie se vyskytovaly v přirozených stepních biotopech. Průměrná nadmořská výška lokalit byla 317 m (rozpětí 155–648 m n. m., medián 260 m n. m.). Získané informace upřesňují současné znalosti o výskytu sysla obecného na území ČR, avšak upozorňují i na prohlubující se závislost jeho současné existence na činnosti člověka a bohužel i na stále pokračující trend úbytku jeho kolonií. Zdánlivý nárůst počtu kolonií totiž není spojen se vznikem nových, ale pouze s objevením dosud neznámých lokalit.

## ACKNOWLEDGEMENTS

We thank V. VOHRALÍK (Faculty of Science, Charles University, Prague) for his support during the study and useful comments on the paper. We are also indebted to all colleagues, who helped us with the field work and provided us with their data. The study was supported by the Ministry of the Environment of the Czech Republic (grants Nos. VaV/620/1/03 and SP/2d4/61/08).
