

TALPA MASINII N. SP., A NEW FOSSIL MOLE SPECIES FROM THE LATE VILLANYIAN FAUNA OF RIVOLI VERONESE (NORTH-EASTERN ITALY) IN THE CONTEXT OF THE EUROPEAN FOSSIL RECORD OF GENUS TALPA

MARCO MARCHETTI

Via Casaline 39, 37014 Castelnuovo del Garda (VR), Italy; e-mail: marcopaleo@hotmail.com.

Marchetti, M. (2024): *Talpa masinii* n. sp., a new fossil mole species from the late Villanyian fauna of Rivoli Veronese (north-eastern Italy) in the context of the European fossil record of genus *Talpa*. – Fossil Imprint, 80(2): 285–311, Praha. ISSN 2533-4050 (print), ISSN 2533-4069 (online).

Abstract: Rivoli Veronese (Verona, north-eastern Italy) is a karst fissure filling that yielded an Early Pleistocene fauna, including many remains belonging to the genus *Talpa*, assigned to the late Villanyian rodent age. Some of these remains, characterized by tiny size and primitive features, were already in the past suggested to represent a new mole species. To better characterize this mole, a re-analysis of the most representative fossil and living populations of the genus *Talpa* was performed. This allowed confirmation that it represents a new species, which was named *Talpa masinii* n. sp., to infer that this species existed in earlier periods in Central Europe too, and to better define the taxonomy and biochronology of the fossil *Talpa* populations.

Key words: *Talpa*, taxonomy, biochronology, Early Pleistocene, Europe

Introduction

Today, the genus *Talpa* includes several species widespread in Europe and north-western Asia, and only one in Central Siberia (Loy et al. 2005, Colangelo et al. 2010, The IUCN Red List of Threatened Species. Version 2021-2. <https://www.iucnredlist.org>). It is one of the most fossorial representatives of the family Talpidae (Piras et al. 2012). The adaptation to the fossorial style of life triggered a strong specialization of the postcranial elements, while the cranium retained primitive characteristics, so much that elements such as teeth did not evolve enough to generate important morphological differences among species to be useful in distinguishing between species, with some exceptions. Because the genus *Talpa* is rather conservative, the specific identification on skeletal remains is often difficult and is usually based merely on morphometric and few morphological features (Fanfani 1999).

The earliest recorded species is the fairly small *T. tenuidentata* ZIEGLER, 1990, a species still not fully adapted to a fossorial lifestyle, and somewhat intermediate in morphology between Talpini and Scalopini (Hoek Ostende and Fejfar 2006, Klietmann et al. 2015), which lived during the Early Miocene, from MN 2 (Ziegler 1990) to MN 3 (Hoek Ostende and Fejfar 2006) (the adopted biochronologic and chronostratigraphic subdivisions are

specified in the Material and Methods section). Since MN 3, if not already in MN 2, the long-lasting (up to MN 11) tiny *T. minuta* BLANVILLE, 1838, already fully adapted to digging, became a common species (Ziegler 2003, 2006, Klietmann et al. 2015). Larger unnamed forms appeared occasionally during the Early Miocene, since MN 3 (Klietmann et al. 2015). However, they became more common only from the Middle to Late Miocene, from MN 7+8 to MN 12, first with *T. vallesensis* VILLALTA et CRUSA FONT, 1944, and later with *T. gilothi* STORCH, 1978 and *T. aff. gilothi* (Storch 1978, Fejfar and Sabol 2005, Hoek Ostende and Furió 2005, Ziegler 2006, Ménouret and Mein 2008, Rzebik-Kowalska and Rekovets 2015). New species emerged around the Miocene/Pliocene boundary (MN 13/14; Doukas et al. 1995), and with even larger representatives, during the Pleistocene (MN 17 to MQ 2).

Especially the Plio-Pleistocene *Talpa* species were emphasized to be recognizable primarily on morphometric criteria, and accordingly grouped into three size groups: small, middle and large (Niethammer 1990, Fanfani 1999, Cleef-Roders and Hoek Ostende 2001). *T. minor* KORMOS, 1930 (senior synonym of *T. gracilis* KORMOS, 1937 according to the majority of the authors; see discussion in Cleef-Roders and Hoek Ostende 2001) and *T. neagui* RĂDULESCU et SAMSON, 1989 are assigned to the small category; *T. fossilis* PETÉNYI, 1864 (senior synonym of *T. praeglacialis* KORMOS, 1930

and *T. europaea* var. *major* FREUDENBERG, 1914 according to the majority of the authors; Kretzoi 1938, Heller 1958, Koenigswald 1970, Rzebk-Kowalska 2013) to the middle category; and *T. episcopalis* KORMOS, 1930 and *T. romana* THOMAS, 1902 to the large category. *T. csarnotana* KRETZOI, 1959 was initially placed alternately into the small (Kretzoi 1959) or middle (Sulimski 1962) category but, since Storch (1978) gave its measurements, it has been placed into the middle category. The Würmian *T. magna* WOLDŘICH, 1893 would fit in the large category. However, it is interpreted as an expression of the high size variability of *T. europaea*, in the absence of any morphological difference, being only slightly larger than the recent populations of the latter species (Stein 1955, Koenigswald 1985).

According to many authors, such as Doukas et al. (1995), Cleef-Roders and Hoek Ostende (2001), Angelone et al. (2011), and López-García et al. (2024), the taxonomy of the fossil representatives of the genus *Talpa* is still confused and needs revision, with significantly varying opinions among authors (see for example Cleef-Roders and Hoek Ostende (2001) versus Sansalone et al. (2015) about *T. fossilis* and *T. europaea* synonymy). It suffers from important deficiencies as well. For example, usually the type population of *T. fossilis* from Beremend 1 (early Villanyian – MN 16a) is notably absent, or merely mentioned in later works. The cause is that the given description and measurements in the rather old work (Petényi 1864) are outdated, hardly comparable to those of the other fossil *Talpa* populations studied later. Actually, the morphological traits and morphometric landmarks that are currently regarded as important for species discrimination were not defined in that work. Furthermore, Petényi's use of archaic language and ancient units of measurement complicates easy comparison with the remains described by later authors. In fact, later authors assigned to *T. fossilis* some remains they studied solely on the basis that they were observed to be of comparable size with recent *T. europaea*, like the type population was emphasised by Petényi to be, without making a direct morphometric comparison between these remains and those of the type population. That way of reasoning represents an oversimplified and potentially problematic approach to species identification. Therefore, the type population is omitted also in this work, because of the above-mentioned not fully reliable data in Petényi's paper, and needs a total revision that is beyond the scope of the present work. The consequence is that, for the time being, the specific attribution to *T. fossilis* of all the other fossil populations later assigned to that species remains ambiguous and provisional.

In summary, the above-mentioned confusion is due to: the poor morphological variation and strong overlapping in size among *Talpa* species; the scantiness and fragmentary nature of remains in the fossil faunas – the reason why many fossil species were established only on poor remains, mainly or only represented by the robust humeri; the lack of any report of diagnostic morphometric measurements and morphological features of some mole populations in older and sometimes also in modern literature; the absence in some papers of the used protocol of measurements, especially in those older than the paper of Hutchison (1974), which is since then used as the source for measuring methods on talpids; the general comparison of fossil species with recent

ones; the nearly complete absence in later works of a critical revision of old literature; and, finally, the poor interest in the study of *Talpa* genus, because that genus was depicted to be useless for biochronological purpose.

Hutchison (1974), Fanfani (1999), and authors cited in the latter paper proved that some humerus linear measurements and ratios (length, diaphysis width, distal width, length vs. diaphysis width ratio, and index of flattening), the femur and radius length, the height of the mandible below m2, and the length of the lower molar row are all morphometrical characteristics useful to distinguish among the different species. Moreover, from a morphological point of view, they showed that the shape and position of the pectoral tubercle in the humerus and the number of mental foramina are useful for the taxonomical purpose as well. Conversely, for example, teeth morphology is less useful to discriminate between *Talpa* species.

Because of the above-mentioned lacunas, the re-analysis of the Plio-Pleistocene remains, by means of the above-mentioned measurements, ratios, and features, is made to try to adjust the taxonomy of the fossil populations of that period, and to get it into the proper biochronological context.

The tiny *Talpa* from Rivoli Veronese site is analyzed in the above-mentioned background. Rivoli Veronese is a karst fissure filling, exposed in a limestone quarry 18 km NW from Verona (north-eastern Italy), containing a late Villanyian – MN 17 (chronologically corresponding to the first half of the Early Pleistocene, i.e., to the Gelasian Stage) small mammal fauna retrieved from a 2 m-high portion of the lower fissure infilling. The absence of a stratified sequence together with a coherent fauna suggested that the fissure infilling was a rapid and single event (Berto et al. 2022). The mole remains from Rivoli Veronese were already partly studied by Fanfani and Masini (1997) and Fanfani (1999). They recognised only two mole species: one, characterised by a tiny size, was assigned to *Talpa* sp., although it was assumed to probably represent a new mole species; the other was assigned to the small *T. minor*. Berto et al. (2022), who made the revision of the fauna, recorded a third mole species, the middle-sized *T. cf. fossilis*, within the remains previously assigned to *T. minor*, and confirmed that the tiny specimens represent a new species of *Talpa*, but did not name it, leaving the matter to the present study.

The above-mentioned re-analysis demonstrates, despite all its limitations, both intrinsic (poor morphological variation and strong overlapping in size among *Talpa* species) and extrinsic (lack of revision on modern grounds of the type populations of some fossil species), that the taxonomy of many fossil remains of *Talpa* can be fixed, that the genus can be useful for biochronological discussion, and that the new tiny species from Rivoli Veronese, here described and named, is recognised in other fossil populations as well.

Material and methods

To better define the taxonomy of the new species, the mole remains from the most representative fossil and living mole populations were re-analysed. This comparison was made gathering from literature (Tab. 1, App. Tab. A1) the most significant morphometrical and morphological

the present work, was needed as a starting point to study in the future these collections one by one, by anyone who can access them.

The findings containing only a few dental elements with no mandibles and humeri hamper precise identification of

talpid assemblages. Therefore, they were omitted from the re-analysis.

T. vallesensis and *T. tenuidentata* were not considered, because the combination of their size, proportions, and age excludes them from the purpose of this work. *T. tyrrhenica*

BATE, 1945, a Middle to Late Pleistocene insular endemism of Corsica and Sardinia (Pereira et al. 2001, Palombo 2006), probably descending from a still unrecognized Miocene species that migrated there during the Messinian salinity crisis (Made 1999), or less convincingly, from a form similar to *T. minor* that migrated there during the sea regression during the “Middle Pliocene – late Ruscianian – late MN15” (Palombo 2006) / “Early/Middle Pliocene” (Furió and Angelone 2010) (Early/Late Pliocene according to the here adopted chronostratigraphic scheme), was excluded as well. *T. stromeri* BRUNNER, 1950, a species of indefinite age, Pliocene according to Fanfani (1999), Biharian (late Early or early Middle Pleistocene) according to Reumer (1995), poorly studied, and of ill-defined systematic position, needs revision and was also excluded from the present work.

The re-analysis allowed adjustment in the taxonomy of some poorly representative fossil populations (represented by scanty remains or by sketchy description) that were misinterpreted in the past, because of being compared against only a partial set of the mole record. In fact, I made new species assignments for these populations (Tab. 1, App. Tab. A1) on the basis of size comparisons and reasoning similar to what past authors did when they assigned those remains to particular species, but comparing them with a broader mole record.

The characteristics, cited in the Introduction section and established by past authors to be of diagnostic importance for discrimination among fossil moles were respectively measured on and described for the Rivoli Veronese remains, too. For this purpose, measuring methods and terminology employed in the text were those used by Hutchison (1974) for postcranial bones, and by Reumer (1984) for mandibles and teeth, because their methodology is widely adopted by the majority of authors who study fossil talpids. By checking all the literature here analysed, the measuring methodology of earlier authors was seen to not differ much from that used by Reumer and Hutchison. Therefore, it was inferred

that most of the measurements taken by past authors were obtained with the same or, in the worst case, with a similar protocol, with a few possible exceptions in the earliest works. This should not have introduced too much bias into the current re-analysis.

Measurements, in millimetres, taken on Rivoli Veronese mole remains were determined using a Parker Hannifin M4000DM Series Digital Micrometer. They are shown partially in Appendix, Table A1 (for comparison purpose with the other European *Talpa* populations) and fully in Table 2. The pictures (Text-fig. 10) were taken with a Leica EZ4HD microscope and processed with ImageJ software.

The biochronologic subdivisions, adopted in this work (Text-figs 1, 2) to cover the long period from the Early Miocene to the present, are built on those of Fejfar et al. (1998), and supplemented following the works of Rabeder (1981), Jánossy (1986), Fejfar et al. (1997), Horáček and Ložek (1988), Kordos (1991), Steininger et al. (1996), Tesakov (1998, 2004), Fejfar (2001), Koufos et al. (2005), Tesakov et al. (2007, 2017), and Mayhew (2015). The chronostratigraphic subdivisions of the same time period are those of Cohen et al. (2013).

Systematic palaeontology

Morphometrical and morphological characteristics of the examined mole record are graphically summarized and compared in Text-figs 3–9. They show why some species assignments changed, mostly between couples overlapping in size to a certain degree, such as *T. caeca* and *T. minor*, *T. minor* and *T. fossilis*, *T. europaea* and *T. fossilis*, and *T. fossilis* and *T. episcopalis*, that is, mainly for size reasons. Notably, I consider *T. csarnotana* a synonym of *T. fossilis*, because neither the original vague description (without a diagnosis, illustration, or even type-designation) provided by Kretzoi (1959), nor the measurements, which were

specified by Storch (1978) only many years after the species was erected, of the type population display differences from the latter species. Other adjustments in taxonomy are cited in the text.

Text-figs 3–9 also show that the smallest remains from Rivoli Veronese are distinctively smaller than and morphologically different from any so far recognized tiny to small mole species.

The whole re-analysis permitted better definition and summarization of the characteristics among the tiny to middle-sized *Talpa* species as well, allowing better differentiation among those species (Tab. 3).

Past works (Fanfani 1999, Berto et al. 2022), together with this re-analysis showed that, among the 68 mole remains from Rivoli Veronese, 12 of them belong to the new species.

postcranial elements, bearing at least up to three mental foramina and the pectoral tubercle of the humerus positioned in a rather variable position (central in some specimens, lateral in others).

Differential diagnosis. It differs from the similarly-sized *T. minuta* BLAINVILLE, 1840, as described

by Hutchison (1974) and Ziegler (2003, 2006), because the only teeth available for comparison (p3 and m2) are distinctively smaller than those of *T. minuta*, while the Lm1 is, conversely, somewhat larger (even more so, because derived from alveolar length); furthermore, in *T. masinii* n. sp. the pectoral tubercle is in a central to lateral position,

Text-fig. 3. Diagram of diaphysis width vs. maximum length of humerus in fossil and recent *Talpa* (acronyms of localities in Tab. 1).

while in *T. minuta* it is always centrally placed; additionally, the former mole, though this observation is based on one individual, bears three mandibular foramina, whereas the latter mole consistently exhibits only two mandibular foramina.

The small species, *T. neagui* and *T. minor*, are found respectively during the Ruscinian – MN 14–15 and since the early Villanyian – MN 16 to Toringian – MQ 2. Reference populations of the former species are those from Bereşti (type locality), Măluşteni, Węże 1, and Podlesice (Rădulescu and Samson 1989), all well described and rich in number of remains. Reference populations for the latter species are mainly those from Erpfingen 3 (Heller 1958), Petersbuch 1 (Koenigswald 1970), Hundsheim (type locality) (Rabeder 1972), Betfia (Rzebik-Kowalska 2000), Žabia Cave (Rzebik-Kowalska 2013), and Rivoli Veronese (Berto et al. 2022). The smallest remains from Rivoli Veronese differ noticeably from the two above-mentioned species in their unambiguously smaller size. Only exceptionally, in few cranial and postcranial elements, they reach the size of the smallest specimens of *T. neagui* and *T. minor*. However, when the proportions of the corresponding elements are considered, they totally differ from those of the latter two species. Moreover, the pectoral tubercle of the humerus is positioned in a central to lateral position, while it is always

in a central position in *T. neagui*, and conversely, in a lateral position in *T. minor*.

Because the remains of this tiny mole differ from the other fossil and recent mole species, and are represented by cranial and postcranial remains with a high systematic value among talpids, such as mandibles, and especially, some well-preserved humeri, this definitely supported the past idea that they represented a new species.

Description. All the cranial and postcranial elements are tiny, although they belong to adult individuals. Even those postcranial elements, such as sternum, radius, femurs, and tibia, that basically have no morphological features useful to discriminate among *Talpa* species, can nevertheless be assigned to the new species. In fact, they are distinctively smaller than those from Rivoli Veronese assigned to *T. minor*, or those from the collection of the Museo di Paleontologia e Preistoria Piero Leonardi of the University of Ferrara belonging to *T. caeca*, a species slightly larger than *T. minor*, collected near Tarvisio (Friuli-Venezia Giulia Region, north-eastern Italian Alps) and in Grotta della Serratura (near Marina di Camerota, Salerno, Campania Region, southern Italy), in strata of latest Pleistocene to sub-recent age.

Mandibles. Based on scanty remains, three mental foramina, one below the original emplacement of m1, between the two alveoli, one below the distal end of the

Table 3. Comparison of characteristics between *T. masinii* n. sp. and other analysed tiny- to middle-sized *Talpa* species. Filling in dark grey: total correspondence of feature with that possessed by *T. masinii* n. sp.; filling in light grey: partial correspondence of feature with that possessed by *T. masinii* n. sp.; no filling: no correspondence of feature with that possessed by *T. masinii* n. sp.; characteristics in bold type: feature representative for the species, because observed in many remains or populations; characteristics not in bold type: features poorly representative for the species, because observed on scanty remains or in few populations.

Features Mole species	Humerus size	Radius length	Pectoral tubercle position	Size graduation of teeth of lower molar row	Number of mental foramina
<i>T. caeca</i>	small	short	lateral	Lm2>Lm1=Lm3	2
<i>T. europaea</i>	medium to large	medium to large	lateral	Lm2>Lm1≥Lm3	2 (3 uncommon)

<i>T. gilothi</i>	small	–	lateral	–	2
<i>T. minuta</i>	tiny	very short	central	Lm2≥Lm3≥Lm1	2

emplacement of p3, one below the original emplacement of p1 and p2, at the boundary of their alveoli.

Teeth. m2 and p3 are badly preserved, so no morphological features can be described.

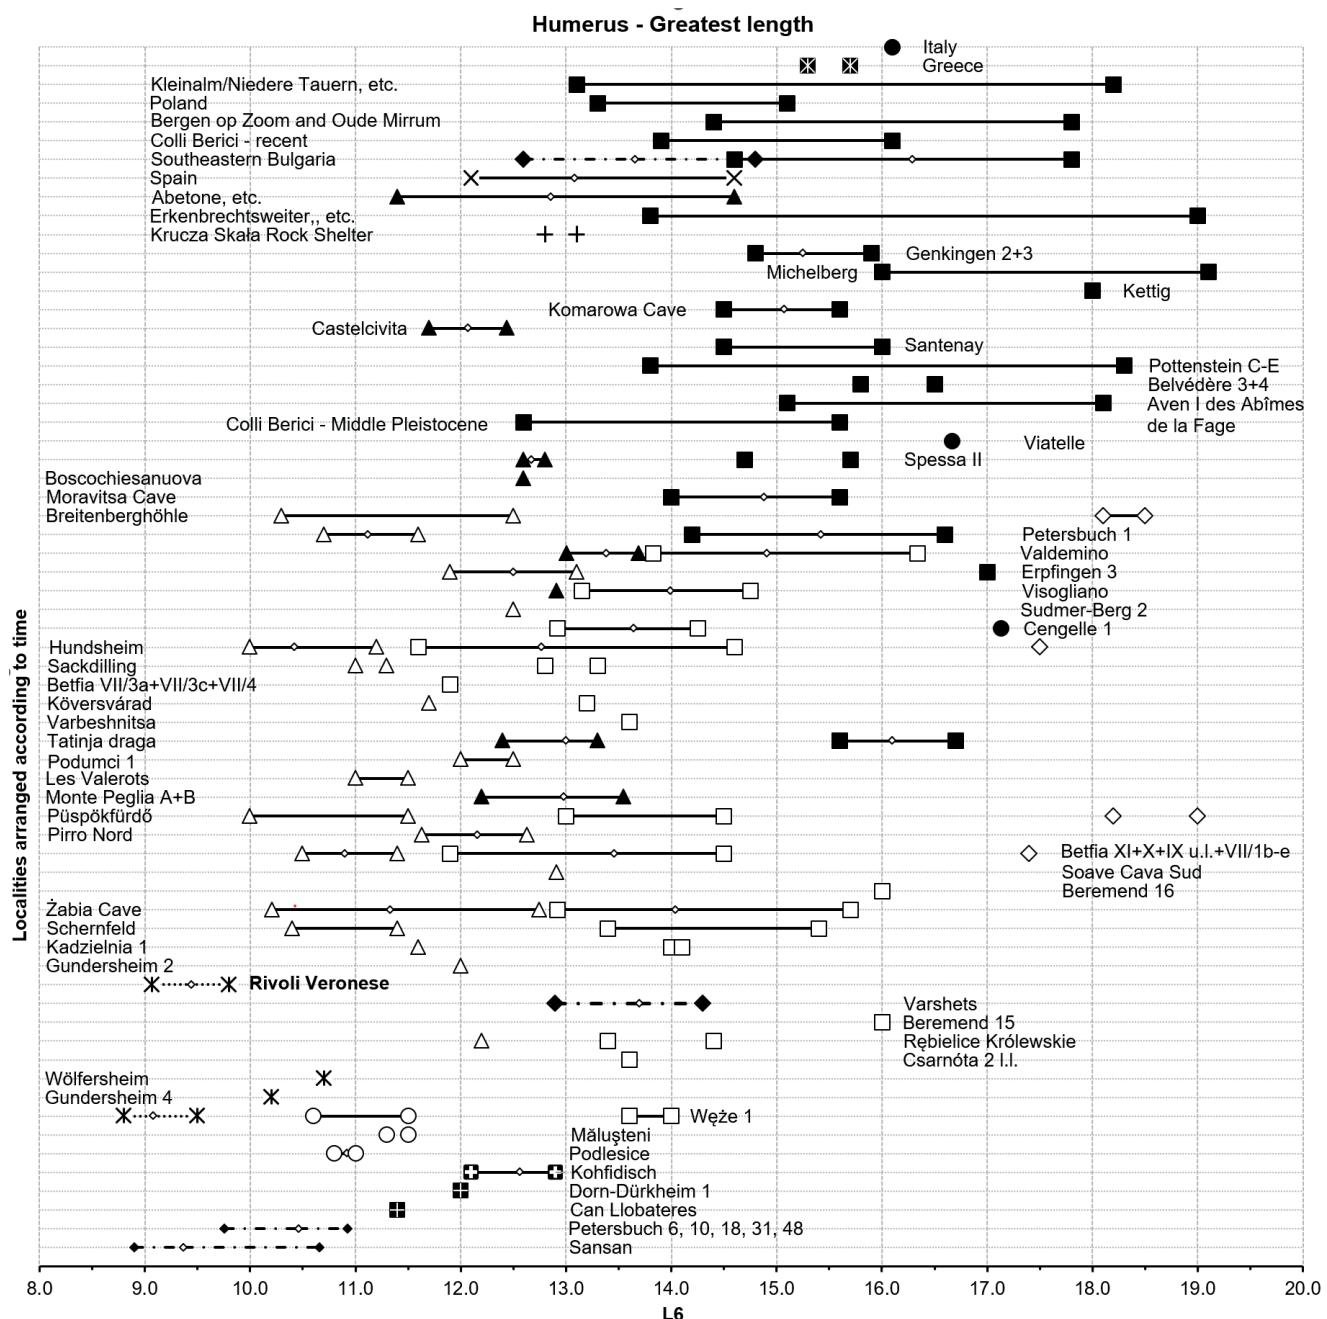

Humeri. V-shaped delto-pectoral ridge; rather variable pectoral tubercle both in outline and position, respectively triangular and in a central position (RV374; Text-fig. 10a), or tongue-shaped and in a lateral position (RV376) (Text-fig. 10c), depending on the specimens; head situated rather laterally; axis of the head subparallel to the long axis from the base to the proximal end.

Related forms. Fanfani (1999) observed on the humeri of the Italian *Talpa* populations an increase of size and robustness, and conversely, a decrease of the index of flattening over time. On the basis of these observations, he showed that the tiny mole from Rivoli Veronese is at the most primitive stage of evolution. An additional primitive characteristic noticeable in some remains from Rivoli Veronese can be considered the central position of the pectoral tubercle, given that this feature is found only in some of the earlier species (Tab. 3). Therefore, I inferred that this tiny mole cannot represent an offspring of any penecontemporaneous species, and thus is not merely an isolated occurrence in the history of moles. Instead, given its primitiveness, it is likely evolutionarily related to earlier populations.

Tiny mole remains were previously found in Central European late Ruscinian – MN 15 to early Villanyian – MN 16 faunas of Węże 1 (Sulimski 1962), Wölfersheim and Gundersheim 4 (Dahlmann 2001), and Hajnáčka 1 (Sabol 2004) as well. Nevertheless, they were assigned to *T. minor*. For example, Sulimski (1962) believed that the smallest humeri and teeth he described from Węże 1 belonged to young individuals of the population of *T. minor*, already recorded by Sulimski (1959) at the site, and later assigned to *T. neagui* by Rădulescu and Samson (1989). Fanfani and Masini (1997) and Fanfani (1999) implicitly rejected this assumption. According to the pictures and the text, even if some humeri seem in fact to belong to young individuals, some others of these supposed young individuals display

the same structure as those stated to represent adults. In that circumstance, individuals with an intermediate size between the supposed young individuals and the adults would have been expected. In any case, no size difference in teeth can exist between young and adult individuals, because in *Talpa*, tooth-succession occurs before birth or, at least, before the time when fur grows upon the young creatures' backs, and milk teeth differ notably from the permanent functional teeth, being rudimental and useless as organs of mastication (Spence Bate 1867, Bolk 1923). Instead, according to the text, the teeth assigned to young individuals are permanent functional teeth while being sharply smaller than those assigned to adult individuals.

As I observed a sharp size difference between the above-mentioned Central European late Ruscinian to early Villanyian moles and the other moles of same age assigned to *T. neagui* and *T. minor* (Text-figs 3–9), I inferred that these tiny moles might represent a new species. Hence, I assumed that they belong to *T. masinii* n. sp., because of the absence of any clear dimensional and morphological difference with the tiny mole from Rivoli Veronese. The large age difference between the above-mentioned faunas and that from Rivoli Veronese cannot be used to reject a specific similarity. In fact, the absence of *T. masinii* n. sp. for such a long time can be explained by the scantiness of *Talpa* remains in faunas of intermediate age, and by the scantiness itself of small mammal faunas from that intermediate time period (Text-fig. 2). Its absence from faunas of intermediate age could also imply that, in later periods, it survived only locally as a Pliocene relict species, like other taxa collected in Rivoli Veronese (*Rhagapodemus* and *Pliopetaurista*; Berto et al. 2022) and in other late Villanyian European faunas (for example, *Blarinoides mariae*, *Sulimskia kretzoi*, and *Deinsdorffia hibbardi* in Poland (Nadachowski 1998), and *Dolomys milleri* in Hungary (Pazonyi et al. 2016)). Finally, I assumed that the smallest humerus (Text-fig. 6) collected at Coste San Giacomo (Bona et al. 2015) might represent an additional late Villanyian record of *T. masinii* n. sp., and thus its southernmost record. As a result, by taking into consideration all the populations here assigned to *T. masinii*

Text-fig. 4. Diagram of greatest length of humerus in fossil and recent *Talpa*.

n. sp., the lower molar row, even if represented by scanty remains, appears to be graded in size with Lm1 > Lm2 and possibly with Lm2 = Lm3.

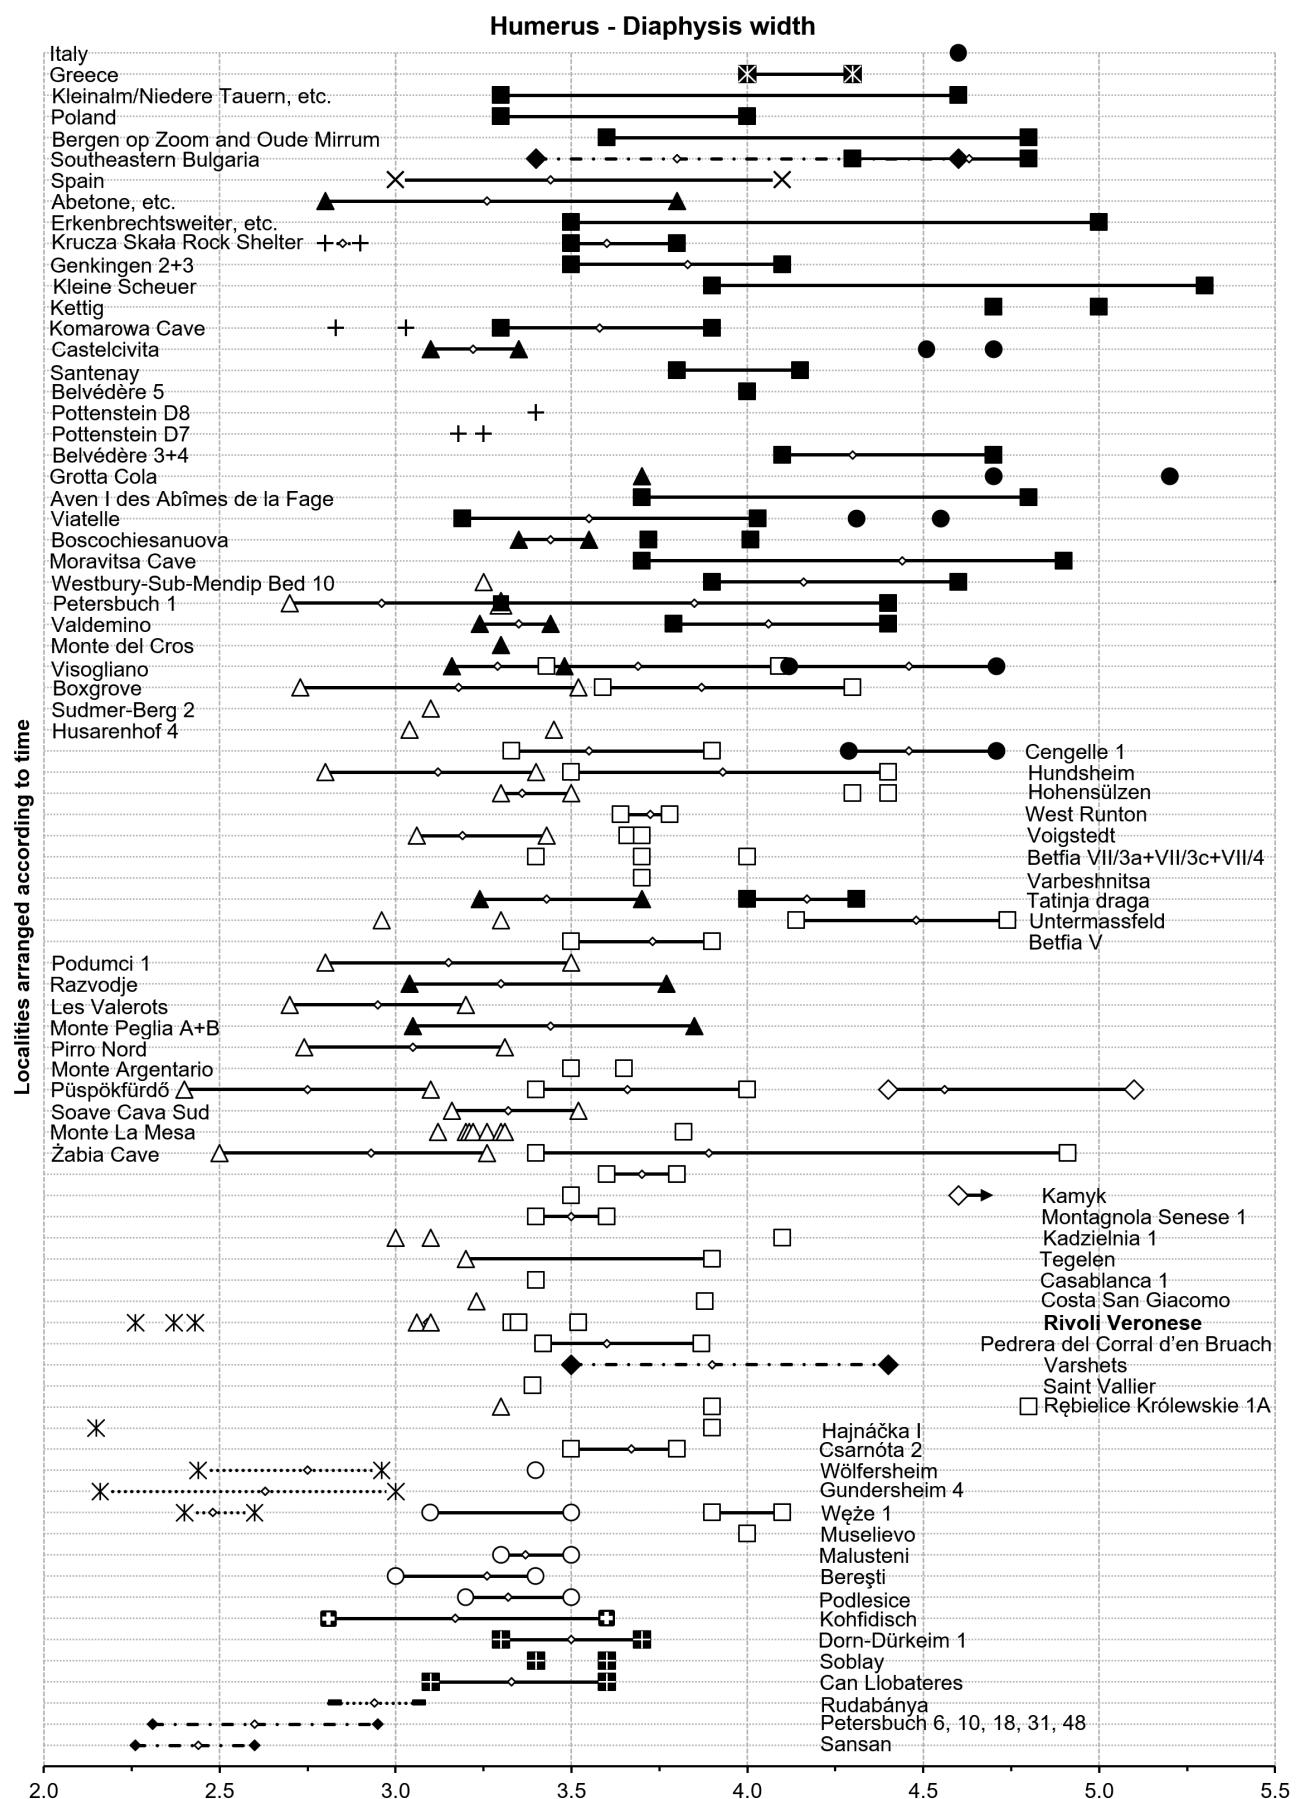

Phylogenetic links. Because *T. masinii* n. sp. shows both similarities and differences in morphology and size compared to both earlier and later tiny to small species *T. minuta*, *T. gilothi*, *T. aff. gilothi*, *T. neagui*, and *T. minor*, with a mixture of features without any apparent ancestor-descendant relationship, this pushed me to exclude a phylogenetic link between *T. masinii* n. sp. and those five species, although *T. neagui* appears to be the species with the greatest similarities, particularly with regard to the size graduation of lower molars (Tab. 3). However, this is a preliminary observation, as the comparison is, in some circumstances, of limited value, due to the scarcity or lack of data regarding some features of these species.

Biochronological range of the new species. From late Ruscinian – MN 15b to late Villanyian – MN 17/1 Rodent Ages (chronologically corresponding to the latest Early Pliocene to early Early Pleistocene Subepoch – latest Zanclean to Gelasian Ages).

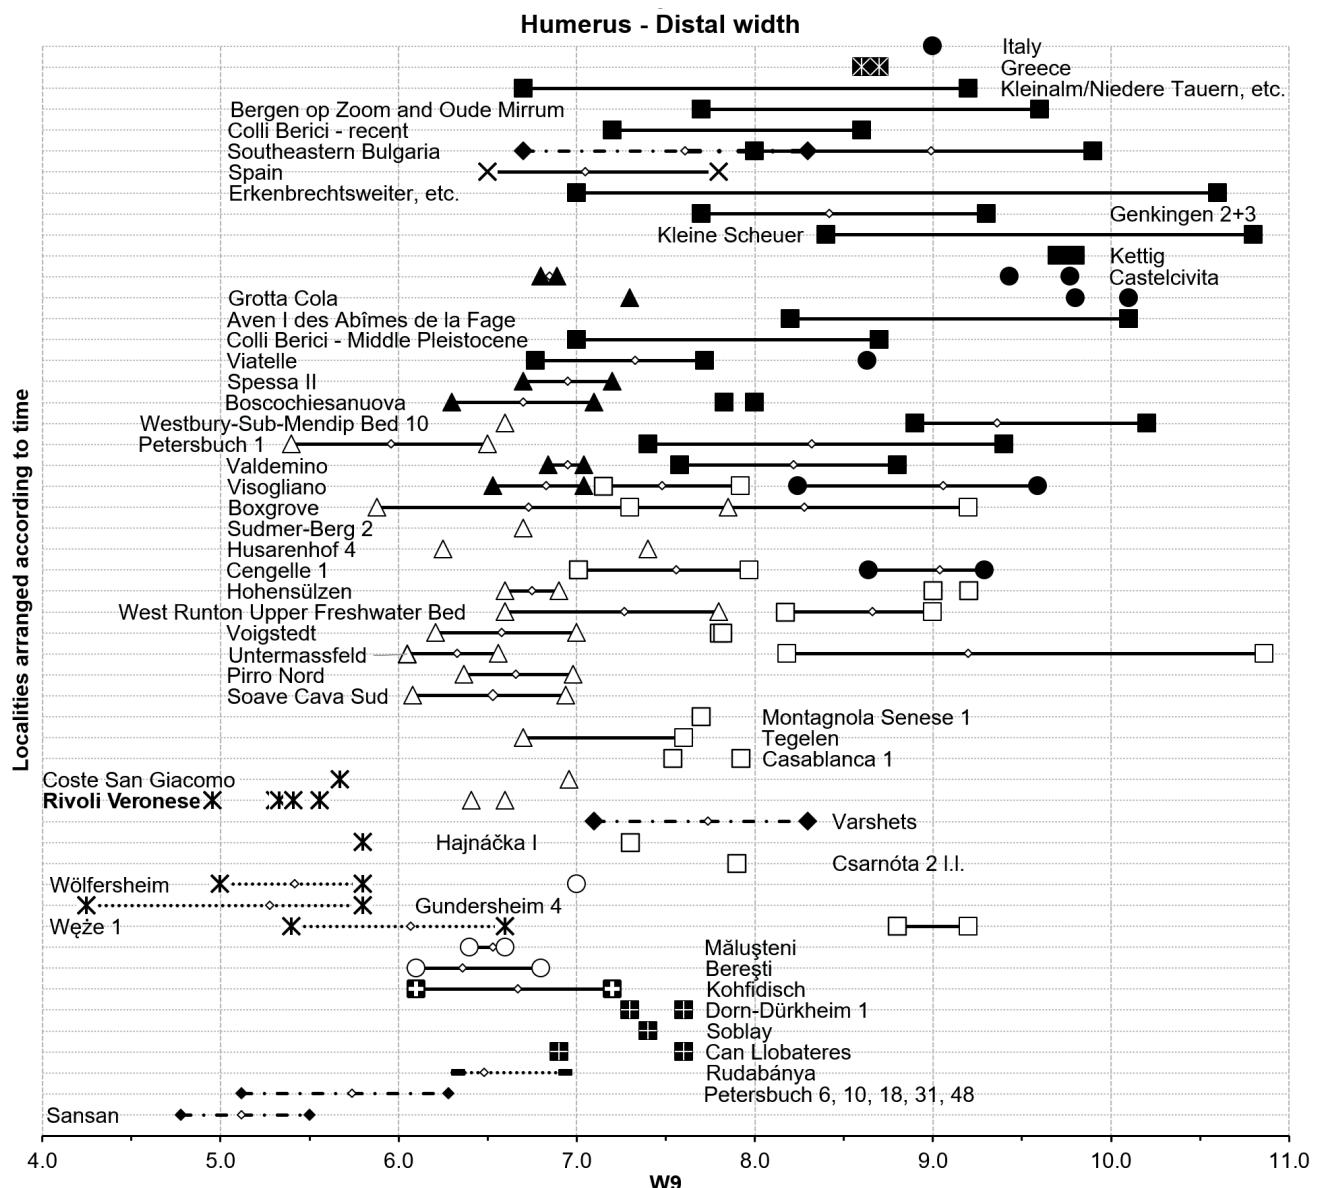

Palaeobiogeographical range of the new species. Central Europe and Italy.

Discussion

The mole remains fitting in the tiny size category from Central Europe and here assigned to *T. masinii* n. sp. were sometimes found associated with those fitting in the small size category that were ascribed to *T. gilothi* in Wölfersheim (Dahlmann 2001) (a species originally described by Storch

Text-fig. 5. Diagram of diaphysis width of humerus in fossil and recent *Talpa*.

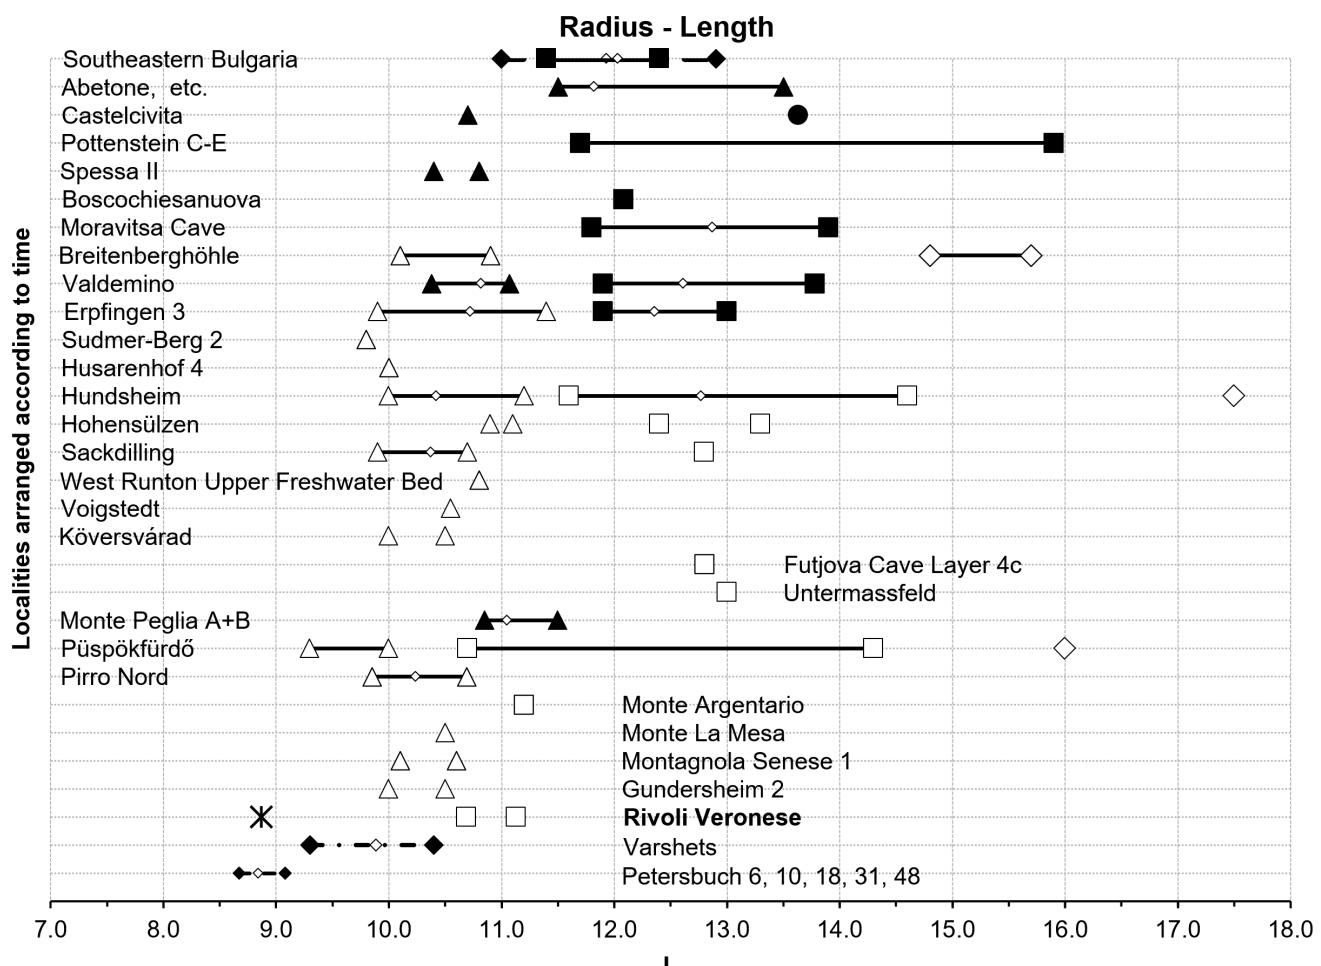

Text-fig. 6. Diagram of distal width of humerus in fossil and recent *Talpa*.

(1978) from the early Turolian Dorn-Dürkeim 1 fauna), and to *T. neagui* in Węże 1 (Rădulescu and Samson 1989). Rădulescu and Samson (1989) observed that *T. neagui* was common and widespread during the Ruscinian, as it was recorded in Berești, Podlesice, Mălușteni, and, possibly, in Musaid (= Musaitu 5) too. It differs from the similarly small Villanyian to early Toringian *T. minor*. In fact, when compared to the latter, it bears: on average, a more robust humerus (L4 in the range of *T. minor*, whereas W1 and W2 in the range between the largest remains of *T. minor* and the smallest remains of *T. fossilis*); a pectoral tubercle with a rather central position (instead of being lateral); and a more gracile mandible with lower molars that, even if based on scanty remains, appears to be graded in size with Lm1 > Lm2 > Lm3, instead of being graded in size with Lm2 > Lm1 = Lm3 (Text-fig. 9). Meanwhile, *T. gilothi* and *T. neagui*, besides differing distinctively in age (MN 10–12 and MN 14–15, respectively), are clearly different from each other in proportions of the humerus and position of the pectoral tubercle (Rădulescu and Samson 1989) (Tab. 3). The humeri from Wölfersheim

equal in size those of *T. neagui* too, and no reason is found to differentiate the remains of Wölfersheim from the latter species. Therefore, all the small remains of Ruscianian age assigned in the past to *T. gilothi* or to *T. minor* should belong to *T. neagui*. The mole remains found in Moncucco Torinese ascribed to *T. minor* by Colombero et al. (2017) may belong to *T. neagui* as well. In fact, although no dimensional data were given by the authors, these remains were described to be smaller than those of *T. gilothi* and *T. vallesensis*, and similar to those of *T. minor* described by Sulimski (1959) from the Pliocene of Poland, the latter remains being merely those from Węże 1, which I here assigned to *T. neagui*, according to the humerus size and proportions. This could imply that the latter species already existed in MN 13.

T. minuta, as an extra note because it is similar in size to *T. masinii* n. sp., is exceptionally mentioned outside the Miocene in the Middle Pleistocene layer 23 of Petralona Cave (Kretzoi and Poulianou 1981). The authors did not give any measurements, but only asserted that it was probably referable to the Middle Pleistocene species *T. minuta* FREUDENBERG.

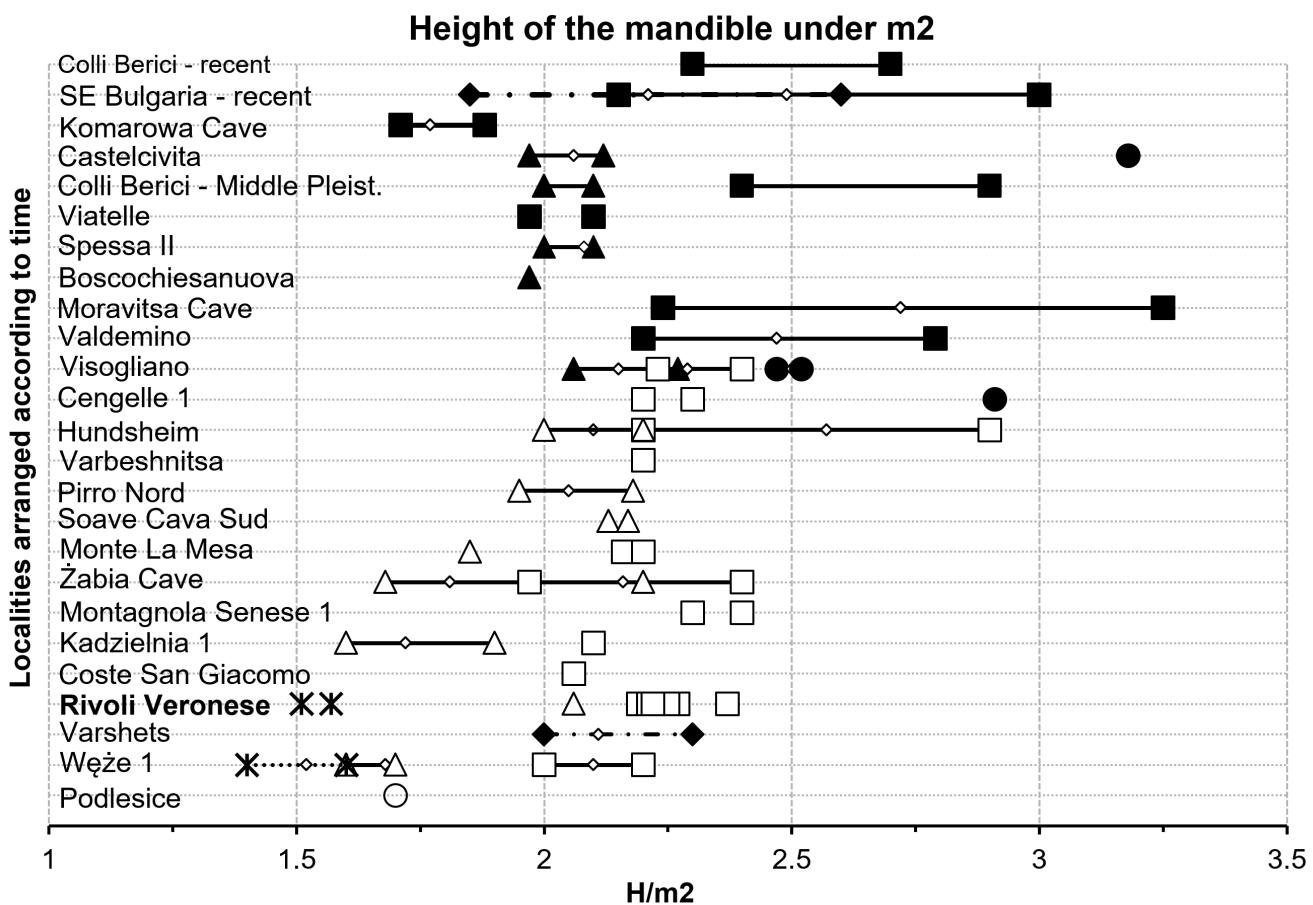

Text-fig. 7. Diagram of greatest length of radius in fossil and recent *Talpa*.

Because Freudenberg was the author who erected the species *T. minor*, whereas *T. minuta* was erected by Blainville, and *T. minor* type population is of Middle Pleistocene age, whereas *T. minuta* lived during the Miocene, I inferred that, in truth, Kretzoi and Poulianou intended to refer it to *T. minor*.

The size of the mole remains from Rivoli Veronese offered new insights into the Plio-Pleistocene mole record regarding size categories. Here three size categories were recognized: one being distinctively smaller than the fossil small size category; one fitting in the fossil small size category; and one fitting in the fossil middle size category. The large size category is missing. Therefore, taking into consideration all the populations assigned in this study to *T. masinii* n. sp., a fourth category existed, the tiny one, not only among the Miocene but also among the Plio-Pleistocene moles.

Rivoli Veronese is thus a site where the coexistence of up to three *Talpa* species is documented within a single fauna. Accordingly to past literature and new species assignments made in this study, three *Talpa* species also co-occurred in Węże 1, Coste San Giacomo, Bettia IX upper level, Püspökfürdő (= Bettia 2), Hundsheim, and Visogliano. Therefore, this is a rare condition, but it is now becoming less unusual in the fossil record. All these faunas were considered assemblages that accumulated over a relatively short period; thus, they are not mixed assemblages. Therefore, this infrequent coexistence rather suggests some form of specialization to avoid competition, particularly considering

that in Europe, sympatry among recent *Talpa* species occurs between a maximum of two species, while syntopy never occurs (Loy et al. 2017). Until now, at least in Italy, the size of mole species has been related to several factors (Fanfani 1999, Loy et al. 2005, Loy 2008), including soil aridity and depth, climate, litter composition, and others; however, no definitive conclusion has been reached. As later discussed by Loy et al. (2017), the reason for the current distribution of European moles is even more complex. Therefore, the coexistence of three *Talpa* species in fossil faunas may have resulted from a mix of factors suitable for each species, either concentrated in one location or, more likely, scattered throughout the catchment area. That area might have been spatially extended both vertically (with the presence of plains, hills, and mountains) and horizontally, encompassing diverse environmental conditions that provided suitable habitats for up to three *Talpa* species. As previously noticed, Fanfani (1999) observed on the humeri of the Italian *Talpa* populations an increase of size, robustness and, conversely, a decrease of the index of flattening over time. This is in line with the trend of increase in size in many mammal species observed by Mazza and Bertini (2012) and Bokma et al. (2016). Additionally, the mole remains from the analysed faunas show a general trend of replacement over time, from Ruscian to present, of small *Talpa* species with larger ones (Text-fig. 2). Fanfani (1999) suggests that the size, robustness and depth of the humerus in moles indicate an

Text-fig. 8. Diagram of mandible height under m2 in fossil and recent *Talpa*.

evolutionary trend linked to the transition from soft, moist soils, more suitable for small moles, to hard, arid soils, which are better suited for larger moles, resulting from the increasing aridity observed from the Pliocene to the present day. Analysing the cited literature, the aforementioned reasons for geographic distribution appear, in some cases, to contrast with the general trend of evolution, as they are influenced by a complex combination of factors.

For now, the origin of *T. masinii* n. sp. remains unknown, as indicated by the discussion in Phylogenetic links of Systematic Palaeontology section and because the limited records of small *Talpa* species during the long period from MN 12 to MN 14, spanning about four million years, are described either poorly or not at all.

Conclusions

The Rivoli Veronese fauna filled a gap in our understanding of the history of the genus *Talpa* in Europe as, up to now, the period from the early to late Villanyian yielded only scant faunas containing significant or described mole remains.

Based on the bibliographical analysis of numerous fossil populations, I proposed some changes in the taxonomic attribution of the moles recorded in certain faunas. This permitted:

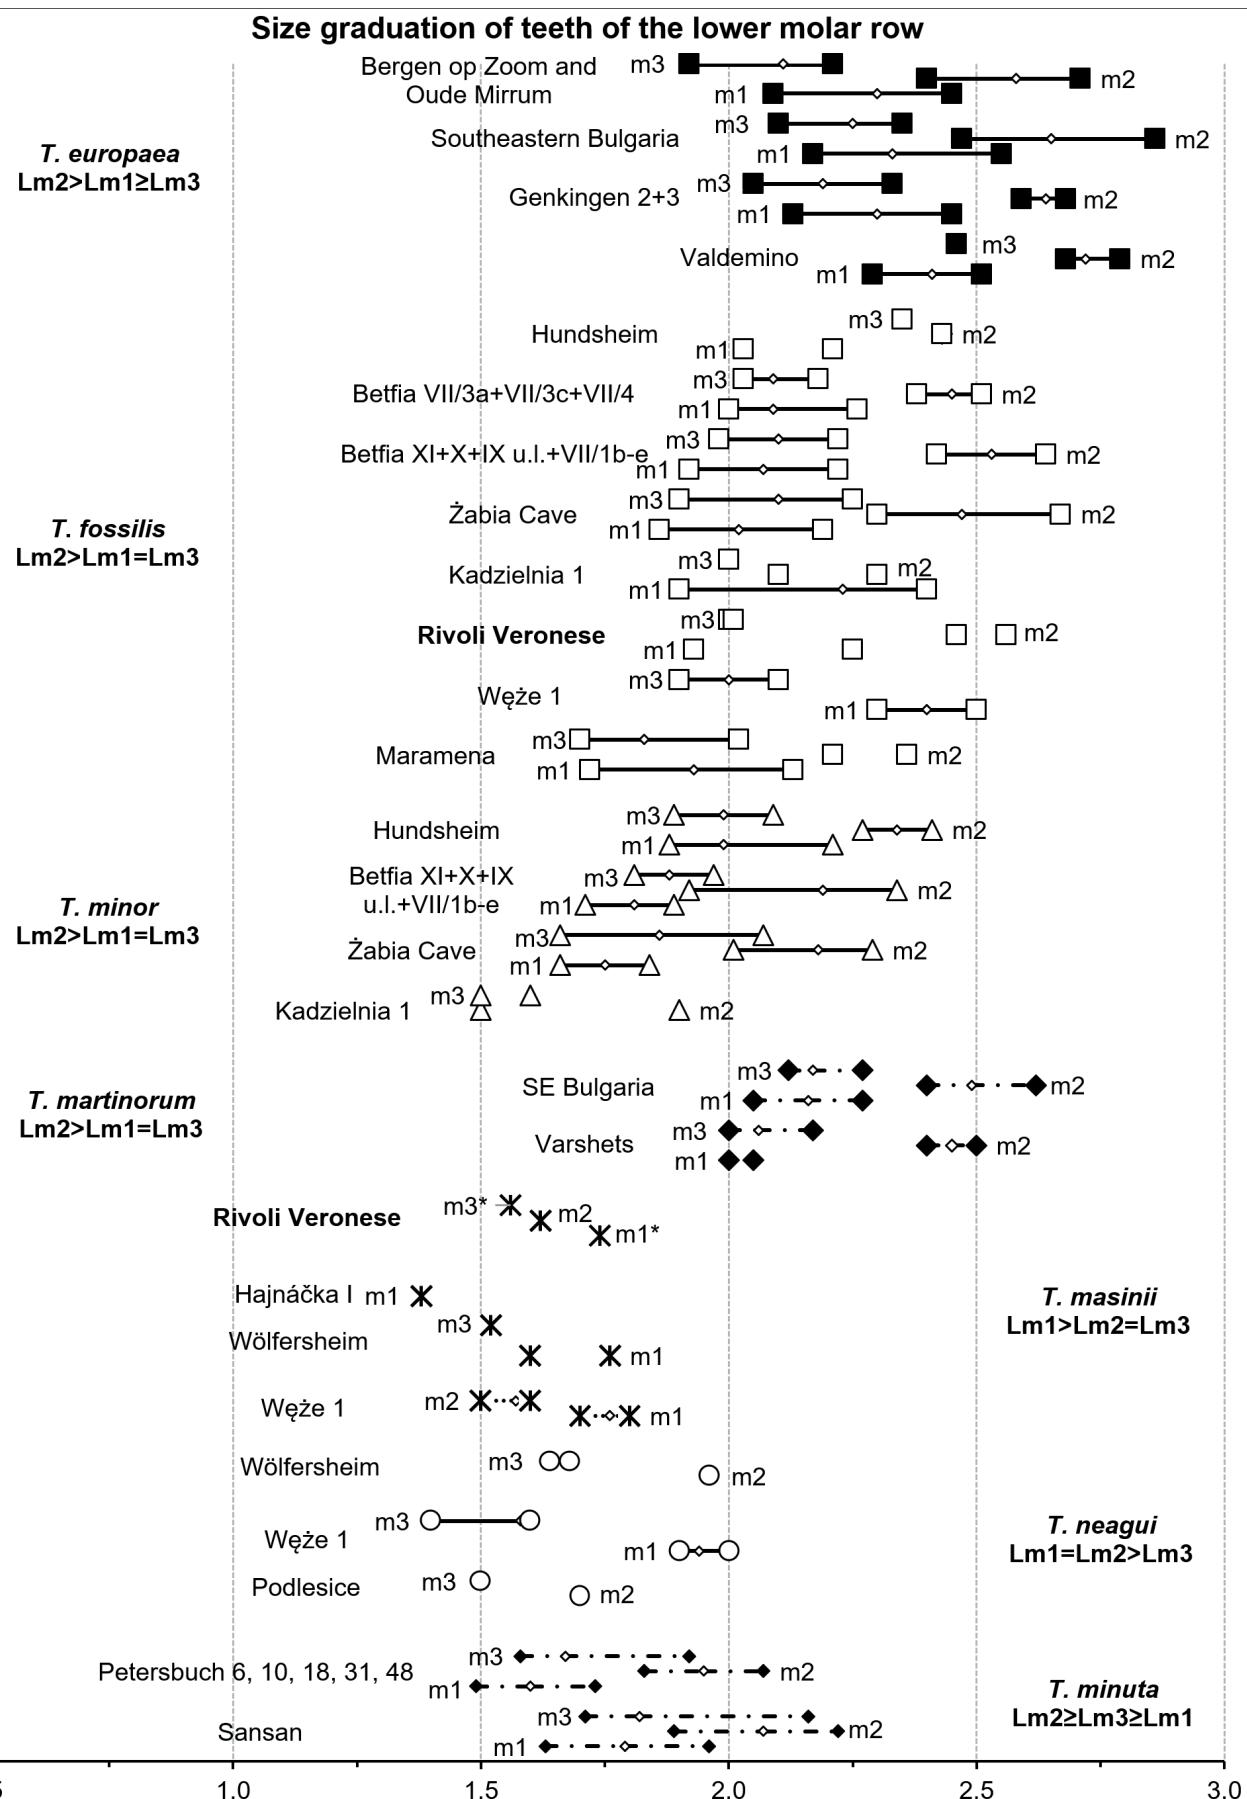

- to attest that the coexistence of up to three *Talpa* species in a local fauna (with no mixed assemblage) was not an exception in the history of the genus *Talpa*;

- to extend the existence of tiny moles up to the late Villanyian;
- to stress that the usual dimensional and morphological characteristics, plus some new ones here used, are helpful to some extent to discriminate the species among fossil *Talpa* populations;
- to recognize, by more precisely fixing the taxonomy and the biochronologic age of the examined *Talpa* populations, that the genus *Talpa* is useful for biochronological inferences.

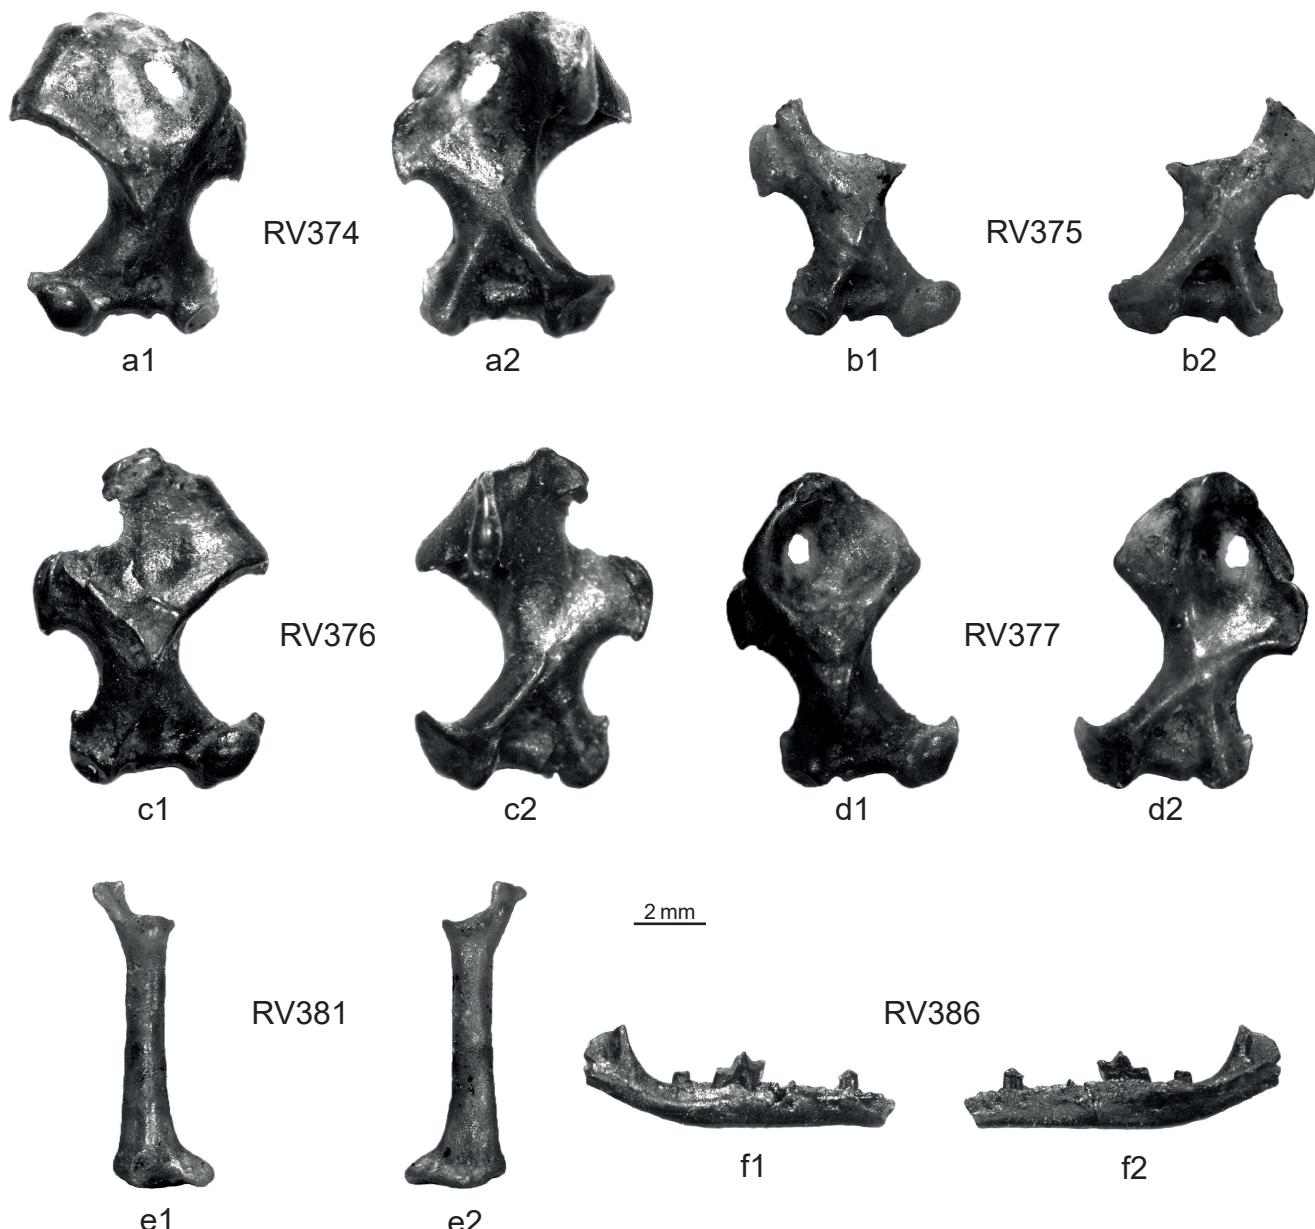

However, the scantiness of fossils remains, and the summary descriptions existing in literature prevent, in some circumstances, solid conclusions, unless a direct revision of the old collections is carried out, in particular those of the type species populations. Thus, the objective to give a comprehensive picture of the evolution of the genus *Talpa* is far from being achieved, also because the present considerations covered mainly those species and populations of interest for the present work. More specific inferences on single species that might be or have been derived from the exposed data need further discussion. All this requires further study.

Acknowledgements

I am deeply grateful to Prof. Benedetto Sala of the Museo di Paleontologia e Preistoria Piero Leonardi of the University of Ferrara for allowing me to study the Rivoli Veronese collection, and for providing access to his extensive
