PLANTAE ČECHOSLOVACAE EXSICCATAE

ED. CUR. SECTIO BOTANICA MUSEI NATIONALIS PRAGAE

Centuria III.

No. 201 – 300

After several years' pause, the Botanical Department of the National Museum is continuing the edition of specimens for exchange. Some older collections of K. DOMIN and V. KRAJINA (prepared for their unpublished series "Flora Čechoslovenica exsiccata") have also been used in this — in total third — centuria. The material for this centuria was collected by the following botanists: B. ALBLOVÁ, J. ČERNÝ, V. CHÁN, A. CHRTKOVÁ-ŽERTOVÁ, M. DEYL, K. DOMIN, J. DOSTÁL, E. HABROVCOVÁ, J. HOLUB, V. JEHLÍK, J. KAISER, KETTNEROVÁ, I. KLĀŠTERSKE, L. KRAJCR, V. KRAJINA, M. KRÁL, S. KUČERA, H. LAUS, A. MARGITTAI, J. MEISNER, J. MĚSÍČEK, J. NITKA, V. PAVLÍČEK, J. ROHLENA, J. SCHEFFER, J. SCHUBERT, P. SILLINGER, J. SOJÁK, J. SUZA, J. UJČÍK, V. VAŠÁK, and F. WEBER. Critical remarks have often been appended to the remarkable taxa or to finds important from the standpoint of phytogeography. The authors of these remarks are: A. CHRTKOVÁ-ŽERTOVÁ, M. DEYL, J. HOLUB, L. HROUDA, I. KLĀŠTERSKE, V. SKALICKÝ, B. SLAVÍK, M. SMEJKAL, J. SOJÁK, V. VAŠÁK, and V. ZELENÝ,

The National Museum in Prague, Division of Botany

Die 23. VIII. 1963

Leg. J. Soják

An East-Carpathian endemic plant distributed from easternmost Slovakia to Romania. A map of its distribution area is given by SZÜCS (1943). Opinions on its taxonomy are very different; most frequently, however, it has been evaluated as a species, or joined as a subspecies either to *A. paniculatum* LAM. or to *A. toxicum* REICHB. GÖTZ (1967) regards it to be a hybrid between *A. paniculatum* (ssp. *paniculatum*) and *A. variegatum*. It is beyond the scope of this brief annotation to take a responsible stand to the phylogeny of *A. lasiocarpum*; but I regard it as necessary to point out that even if Götz's opinion is correct and *A. lasiocarpum* is really of a hybrid origin, it now represents an already fixed taxon which occurs quite independently of both supposed parent species and in the territory of the East Carpathians it behaves as an independent taxon. On the basis of observations carried out on the Nízké Poloniny Mts. (= Bieszczady Zach. — the westernmost part of the East Carpathians) I assume that *A. lasiocarpum* is either species, or it could possibly be ranged as a subspecies to *A. paniculatum* (not to *A. toxicum*). *A. lasiocarpum* differs from *A. paniculatum* in no other character than in the indumentum of carpels. This diacritical character is not absolutely constant, it is variable in some cases, and it is possible to find transitional types. Its classification under *A. toxicum* seems to be less suitable, the shape of bracteae in this species being substantially different. In Czechoslovakia *A. lasiocarpum* was found for the first time in the Vihorlat Mts. (SZÜCS 1943, MICHALKO 1955), later on the Rabia Skala Mt. in the Czechoslovak-Polish frontier ridge (MÁJOV-SKÝ 1956, SOJÁK 1959). The author of this annotation found the species in other sites of the same frontier ridge else, where it penetrates to

Polish territory (a new plant for the flora of Poland!). The distinct ecological differentiation between *A. lasiocarpum* and *A. paniculatum* occurs in the westernmost part of the East Carpathians: the first species grows predominantly on dry rocky or stony slopes mainly facing the south, while *A. paniculatum*, on the contrary, is a pronounced species of moist habitats — it accompanies exclusively the brooks and spring environs on the slopes facing north (the Polish territory here), and it only rarely reaches to the Slovakian side of the ridge (valley of the Stužica brook).

Leg. E. Habrovcová

According to NYÁRÁDY (1927), this taxon is characterized by lower stem leaves which are shorter and broader than the upper ones, by broader (to nearly orbicular) siliculae, and by larger petals (2.6—3.1 mm in length). As regards its ecology, it is confined first of all to rocky habitats. The typical race ssp. *tortuosum* is a psammophyte: its ground leaves are similar to those on the stems, its siliculae being longish-ovovate and petals smaller (2.2—2.6 mm long). The given locality of *A. tortuosum* ssp. *heterophyllum* represents one of the four localities cited by NYÁRÁDY in the original description of this taxon. After a revision of the herbarium specimens collected in Slovakia I assume that ssp. *heterophyllum* is a taxon which has not yet been fully clarified, and its further critical study appears to be necessary. The individual diacritical features will have to be verified in experimental cultures; they do not seem to be constant. Of course, it is necessary to admit that the plants collected in S. W. Slovakia (ssp. *tortuosum*) possess — analogously with the plants from the Hungarian sands — distinctly smaller petals than the specimens of ssp. *heterophyllum* from the karst slopes of E. Slovakia (Slovakian Karst).

- Anthriscus longirostris* occurs in the warmest parts of Czechoslovakia: in S. Moravia and S. Slovakia, here from the lowlands of Záhorská nížina to the lowlands of the river Tisa; it is relatively copious there, as

a rule as a species of subruderal communities ("Mantelgesellschaften") belonging to the alliance *Alliarion officinalis* OBERDORFER 1957. The native occurrence of this species in Bohemia is not certain; it occurs rather rarely in lower sites (planar and colline belts). In S. Bohemia — where the edited specimens were collected — *A. longirostris* is very rare, and its occurrence here is undoubtedly of a secondary character. Some authors mention the existence of transitional types between this taxon and the very closely related species *A. cerefolium* (L.) HOFFM. — e. g. UECHTRITZ Oesterr. Bot. Zeitschr. 12:87, 1862; NEILREICH Fl. Nieder-Oesterr., 642, 1859. Owing to this fact and to the little morphological diversity of the both taxa (the diversity is based only on the existence of a spiny indumentum in fruits), *A. longirostris* is usually regarded as an infraspecific taxon of *A. cerefolium* (L.) HOFFM., which in Czechoslovakia was known in culture and as an occasional escape only; at present this plant is no longer cultivated here. J. HOLUB

Moravia australis, distr. Břeclav, colles Pavlovské vrchy prope oppidum Mikulov: in abruptis collis Děvín, expos. septentr., in rupibus calcareis, 450—500 m s. m.

Die 28. V. 1932

Leg. H. Laus et F. Weber

The specimen was collected in the only locality known in Czechoslovakia. This locality is very remarkable from the viewpoint of both plant geography and florogenesis and ecology. *A. grandiflora* is a mountain plant, the distribution area of which extends from Algeria, Portugal and Spain to the western borderlands of Yugoslavia. The occurrence on the Pavlovské vrchy hills appears to be the northernmost enclave of the area. The nearest localities are situated in the Austrian Alps (Raxalpe, Schneeberg). In southern Moravia, *A. grandiflora* represents a significant glacial relic. It occurs here in a region which belongs to the warmest of Czechoslovakia and grows in the close vicinity of pronounced xerothermic steppe communities. Its habitat, however, are the limestone rocks facing the north; its occurrence at altitudes of less than 500 m a. s. l. is therefore influenced to a high degree by the microclimatic

conditions. The occurrence of *A. grandiflora* on the Pavlovské vrchy hills has been known for more than 100 years (cfr. MAKOWSKI 1863), and it is to be found rather frequently on the locality up to the present day.

Campanula barbata L.

Silesia, montes Hrubý Jeseník, Karlova Studánka: in pratis montanis supra casam "Ovčárna", 1350 m s. m.

Die 25. VII. 1967

Leg. M. Deyl

Campanula barbata is a species interesting from both phytogeographical and ecological viewpoint. In Czechoslovakia it grows only in the Jeseník Mts. (Gesenke) and on the Kladský Sněžník Mt. (Glatzer Schneeburg). It does not penetrate into the other areas of the Sudeten Mountains and of the Carpathians. Its development centre is situated in the Alps, from where it migrated to Czechoslovakia through a narrow passage in the Bohemian-Moravian Uplands. It grows predominantly on acid soils, it very frequently occurs above the forest zone in the herb-rich stands of *Nardus stricta* L. Often it descends into the meadow stands at lower altitudes, sometimes even below 800 m a. s. l. Its localities in Norway are in clear connection with the centre in the Alps, however, its manner of spreading is unexplained. Spreading via the localities in Württemberg or Jeseníky should be taken into account. The absence of this species in the Krkonoše Mts. (Giant Mountains) suggests penetrating through the more northern passage. The possibility of descent into lower regions does not exclude the spreading of the species immediately after the glacial period by following the retreating glacier, the passage ha-

ving been cut off by the subsequent expansion of closed forest stands.
This species is very little variable in Czechoslovakia. M. DEYL

Leg. V. Vašák

A mediterranean forest species; its distribution area extends from Sicily across the Apennine Peninsula to S. Croatia (once it also grew on Corsica). In the Moravian locality it is undoubtedly an escape. It grows here in a mixed deciduous (predominantly maple) forest on humous soil, together with *Paris quadrifolia*, *Anemone nemorosa*, *Corydalis solid*, *Polygonatum officinale*, *Phyteuma spicatum*, *Lathyrus vernus* and other forest species. *C. chelidonifolia* occurs very copiously in the locality, and it seems to spread continually. It is not impossible that it was brought into the locality by the botanist O. LENEČEK from Šumperk since it has been found that *C. chelidonifolia* was grown in the garden of the grammar school at Šumperk in 1931. This locality is at present the only site in Czechoslovakia where the naturalized *C. chelidonifolia* has been found.

Carex rupestris ALL.

Fl. Pedem. 2:264, 1785. — *C. petraea* WAHLENB. Svensk Vetensk. Akad. Nya Handl., Stockholm, 24 : 139, 1803. — *C. drummondiana* DEWEY Amer. Journ. Sci. 29:251, 1836 (incl.).
Slovakia borealis, montes Velká Fatra, distr. Martin: in declivibus saxosis calcareis montis Suchý vrch supra vicum Liptov. Revúce, c. 1550 m s. m.

Die 18. VII. 1936

Leg. J. Suza

Carex rupestris is one of the rarest plants of the Czechoslovak flora; at present it is known from only 8 localities which are mostly of very

tiny area (several square metres only). Besides the occurrence in the Velká Fatra Mts. where the edited plants were collected (description of the habitat see in SUZA J., Příroda, Brno, 24:196, 1931), this species is known from two localities in the High Tatra, three localities in the Belanské Tatry Mts., one locality in the Hrubý Jeseník Mts. (Ash Mountains), and one locality in the Krkonoše Mts. (Giant Mountains). It is not impossible that this species is overlooked owing to its inconspicuous appearance, rare flowering and tiny area of its localities; this opinion is supported by its recent finds in new territories, e. g. in the Swiss Jura, the Abruzzi, the Bavarian Alps, the Zachodnie Bieszczady, the Giant Mountains, etc. The edited material is infected by a parasitic species of the genus *Cintractia* which, according to my observation, in 1959 made reproduction by seed almost impossible in this population. *C. rupestris* occurs on this locality on narrow edges of the dolomitic-limestone rockeries in their upper parts, which are not snow-covered in winter; here it forms almost pure stands with some dispersed species of the communities belonging to the alliance *Caricion firmae* GAMS 1936, to the pioneer stages of which the stands of this species should be counted here. As regards the general distribution, *C. rupestris* belongs to the arcto-alpine (arcto-oreoseptentrional) species which occur both in the Arctic and in isolated localities in the mountains of the northern temperate zone; southwards it penetrates in Eurasia to the Pyrenees, Abruzzi, Carpathians, Caucasus, the Mongolian Altai, the mountains of the Soviet Far East and of the island Sakhalin, on the American continent up to Quebec and to the Rocky Mountains [here it occurs in isolated localities up to the Colorado in a little different type — *Carex rupestris* ALL. subsp. *drummondiana* (DEWEY) HOLUB, comb. nova (Basionym: vide supra!)]. Bulgarian authors [ACHTAROV, Rodat *Carex* (Ostrica) v Bălgarija, 15, Sofia 1957; Välev in Fl. NR Bălgarija 2:70, 1964] give *Carex orbicularis* VELEN. Fl. Bulgar., 575, 1891 as a synonym of *C. rupestris* ALL. Original plants of Velenovský's species (holotype in PRC) belong, however, to *C. curvula* ALL., and were so determined already by KÜKENTHAL (cfr. ENGLER, Pflanzenreich IV., 20, 38:186, 1909). J. Die 10. VIII. 1932

Leg. K. Domin et V. Krajina

The generic name *Chamaenerion* (ascribed to ADANSON or SCOPOLI) has usually been used for the group of species related to *Epilobium angustifolium* L. em. when its separation from the genus *Epilobium* was accepted (ADANSON, SCOPOLI). Considering that this name, when published for the first time (SÉGUIER Pl. Veron. 3 : 168, 1754), and also by ADANSON, SCOPOLI and SCHREBER, was used for the genus *Epilobium* L. 1753, it is illegitimate. In the subsequent literature *Chamerion* (RAF. 1814) RAF. 1833 only exists as a legitimate name which must be accepted as the correct generic name. A more detailed analysis of this problem will be published in another article (HOLUB, Folia Geobot. Phytotax., Praha, 7, 1972, in press). In Czechoslovakia *Ch. dodonaei* is distributed mainly in the Carpathian region, where it occurs on silt alluvia along the water courses in the plant communities belonging to alliances *Epilobion fleischeri* G. BR.—BL. 1931 and *Salicion eleagni* MOOR 1958. Its occurrence of apophytic and locally or regionally neophytic character, first of all in quarries, on pit dumps, gravel heaps etc., is also relatively frequent.

Die 29. V. 1964

Leg. J. Soják

The plant originates from the only autochthonous locality of this species in Czechoslovakia. Discovered in 1927 by F. HAJNÝ, it was later published by DOMIN (1936). The distribution area of the species extends all over S. Europe from where it penetrates into Asia Minor, Syria and Tunisia. The Slovakian enclave is isolated and remarkably remote from the nearest localities in Austria and Hungary, with which it is continuous from the florogenetic point of view. The habitat of *C. emerus* in the Malé Karpaty Mts. is a deciduous slope forest (with the endemic *Sorbus slovenica* KOVANDA) on dolomites. It grows on only one hillside, but it is copious there. The Slovakian plants are always low; however, their other characters (size of leaves and flowers) conform to the typical form of the species.

Die 22. VIII. 1904

Leg. J. Schubert

A subatlantic-submediterranean species; the S. E. extremity of the northern part of its distribution area reaches the territory of Czechoslovakia. This therophyte of moist, sandy or silty soils occurs as a characteristic riverside plant (Stromtalpflanze) along the bigger Bohemian rivers only and links up with the distribution area in the German part of the Elbe basin. All the spontaneous and subs spontaneous occurrence is limited to the banks of the Elbe (Labe) from the state frontier near Hřensko to the town Mělník, and to the bank of the lower part of the Vltava from its mouth into the Elbe up to Prague. A continuation of the occurrence from Mělník up the stream of the Elbe is not impossible. From the viewpoint of nativity of the species in Bohemia, its introduction and subsequent spread by ship transport (which on the Elbe date as early as since the 8th century A. D. from Magdeburg to Bohemia) cannot be excluded. Most finds in Bohemia date back to last century. KLUTSCHAK'S material collected in 1841 on the Elbe island (formerly called "Sandinsel") near Litoměřice should be regarded as the oldest (ANKERT in Nat. u. Heimat 10:39, 1940). The canalization of the river, paving and concreting of the banks, excavation of silt deposits etc., destroyed many suitable ecotopes. The localities in Bohemia are

distributed within the altitudes of about 115 — 185 m a. s. l. As regards the secondary localities, this species is known in Bohemia up to present only from the goods station at Praha-Žižkov (JEHLÍK 1968, PR). Doubtful and quite improbable is the record of SCHLOSSER from the bank of a brook at Horní Bečva near Rožnov in Moravia, dated 1834 (FORMÁNEK Květ. Mor. 2/2:1316, 1897). On the rivers Elbe and Vltava, in their sections where *C. litoralis* is distributed, there is the above-average rate of flow from February to April (germinating period), while in the summer months (July to October), when the plants are developing and their fruits are ripening, the rate of flow has its minimum values.

Die 2. VIII. 1967

Leg. M. Deyl et J. Soják

The given locality is the only one in Slovakia. It was discovered rather late (the oldest material in the Prague herbaria dates from 1931, coll. P. SILLINGER). Even in the other parts of Czechoslovakia is the species very rare. It occurs on several localities in the Krkonoše (Giant Mountains; cfr. JEŇÍK 1961, ŠOUREK 1969), where it has been known since ancient times (it was collected as early as in 1600 and 1786) and in southern Bohemia, where it was found in two localities. In the Šumava Mountains it was discovered by HILITZER (1925) on the precipices of the mountain Jezerní Sténa (on the Bavarian side of this mountain ridge it was known previously: Arber, Keitersberg), and in the Novohradské hory Mts. (Gratzer Gebirge) it was found by DELECHANT (1938) above the village Hojná Voda (Heilbrunn) near the town Nové Hrady. In the localities mentioned here inhabits *C. crispa* exclusively scree, only in the Šumava Mts. does it grow in rock crevices. The map of general distribution of the species was published by FERNALD (1935).

Leg. M. Deyl

Among the edited plants there are to be found numerous individuals with simple, not-branched stems. By this character these plants differ from the type which is usually characterized by stems richly branched from the basis upwards which bear numerous, mostly opposite twigs. The specimens of *E. nemorosa* from more shady and a little moister habitats (e. g. from grassy forest edges and paths, from higher-grown grass stands etc.) are characterized, as a rule, by slenderer, thinner and usually also less branched and often flexuous stems and branches; besides, their bracts are often more conspicuous than in the typical plants spreading obliquely or horizontally or bending down. The typically cleancut plants of *E. nemorosa* grow in our country predominantly in grassy edges of field paths, in pastureland, on village greens etc. The ecological demands of *E. nemorosa* and of the commonly wi-

despread *E. stricta* WOLFF are much alike; however, *E. nemorosa* shows — in contradiction to *E. stricta* — a very pronounced nitrophilous character. *E. nemorosa* is a subatlantic species, the eastern boundary of its distribution area runs partly across the territory of Czechoslovakia. (As to the distribution area of this species, see SMEJKAL in Biologické práce SAV (Biol. Arb. Slowak. Akad. Wiss.) IX/9, 1963; its distribution in Czechoslovakia see idem in Publ. Fac. Sci. Univ. J. E. Purkyně, Brno, no. 452, 1964.)

In Czechoslovakia the species occurs frequently only in the N. E. corner (from the southern foot of the Vihorlat Mts. northwards to the Polish frontier and from the river Laborec eastwards to the Ukrainian frontier), i. e. within the area of the East Carpathian flora. It is rather rare in the other Czechoslovak regions: it occurs in several localities situated between the towns of Rimavská Sobota, Poltár and Tisovec (these localities are apparently connected with the North Hungarian fragment of the distribution area); an isolated locality is known from near Bratislava (Mariánka) where the species probably extends from Austria (cfr. BAREŠOVÁ in HENDRYCH 1969). In our country it grows in deciduous (predominantly beech) forests at the altitudes of 200—960 m. The disjunctive distribution area of this species reaches its northern boundary in the East Carpathians. Our plants were collected near this boundary.

Leg. L. Krajcr

The diacritical characters of all species of the genus *Gentianella* growing in the territory of the Bohemian Massif are given in the table (SKALICKÝ 1969, p. 145). The South-Bohemian plants were most frequently identified as *G. austriaca* (A. et J. KERN.) HOLUB. *G. bohemica* differs from the typical morphotype of *G. austriaca* (from the territory eastwards of the Alps) by having smaller flowers (18—26—35 mm long), sharper incisions (U—V) among calyx-lobes which are papillose, and conspicuously revolute and distinct wings of the calyx tube. *G. bohemica* differs from *G. germanica* and *G. carpatica* by having larger flowers, primarily a longer gynophore, and leaves longer than the internodes.

The characters related to the growth of *Gentianella* species are not reliable. The autumnal morphotypes suffer from mowing and grazing, lateral branches taking on the function of the main stem. As a result the plants are lower and more bushy (so-called "putate forms"). The flowers and leaves of these plants are sometimes a little smaller, but they are typical both for this and for other autumnal types of *Gentianella*. In a given locality they are sometimes to be found more frequently than the plants of normal growth. That is why we have purposely added these morphotypes to the normally developed plants. I assume that it would be more correct to evaluate the species *Gentianella bohemica*, *G. austriaca*, *G. sturmiana* etc. as subspecies. Of course, it would demand a change of the deep-rooted conception, because the value of subspecies in these *Gentianella* species has been used to distinguish the seasonal races (estival, autumnal, monomorphous). Die 20. V. 1967

Leg. J. Soják

Helictotrichon desertorum is a characteristic element of the continental steppes reaching from the regions of Central Siberia and Central Asia to Central Europe. The present material was collected in the arella which is most exposed westwards. In the extensive distribution area the species splits according to the character of ligulae into two complexes, the European—West Siberian (ligula long, toothed, not ciliate), and the Central Asiatic—Middle Siberian (ligula short, at most lobate, ciliate to pubescent). In each of these complexes two taxa are included which differ in the indumentum of the sheaths in culm leaves and are limited only to a part of the distribution area of the species. The following four subspecies belong to *H. desertorum* complex:

1. subsp. *basalicum* (PODP.) HOLUB: ligula long, toothed, glabrous; sheaths of culm leaves hairy; distributed from Bohemia to W. Siberia.

2. subsp. *desertorum* (secundum typum LESSING., LE): ligula long, toothed, glabrous; sheaths of culm leaves glabrous; distributed from the Volga to the promontories of Altai.
3. subsp. *centroasiaticum* HOLUB ined.: ligula short, at most lobate, ciliate to pubescent; sheaths of culm leaves pubescent; distributed from Pamir to Altai and N. Mongolia.
4. subsp. *altaicum* (CVELEV) HOLUB: ligula short, at most lobate, ciliate; sheaths of culm leaves glabrous; distributed from the promontories of Altai to Transbaikalia.

This material was collected in a locality at a distance of only 2 km of the type locality of subsp. *basalticum* in which the diploid chromosome number ($2n=14$) was found. In Central Europe *H. desertorum* represents a relic of periglacial steppes of the late glacial period (cfr. HOLUB Acta Univ. Carol. Biol., Praha, 1962:153—188, 1962). J. HOLUB

Die 2. VIII. 1967

Leg. M. Deyl et J. Soják

The main morphological features of the subspecies: robust, hexaploid ($2n = \pm 54$), perennial plants with a strong, woody rootstock and mostly not-branched stems; the cauline leaves (slightly) fleshy, often shining, sessile, with edge \pm regularly shallowly (sharply) dentate, at the basis mostly without narrow auricles; from the basis to the head the internodes gradually get longer and the leaves decrease in size, so that the stems below the heads seem to be almost leafless; heads large (mostly 4 to 6 cm in diameter), usually single; achenes from the disk about 2.6 mm long, those from the rays usually with an irregularly lobed, membranous calyx soam. This taxon is also distinguishable statistically from the related taxa, based upon the larger size of stomatal guard cells and the bigger diameter of pollen grains. The flowering period (VI.—VIII.) is in average retarded, as compared with the diploid and tetraploid plants.

As regards its distribution, this taxon belongs to the primary penalpines, like e. g. *Bupleurum longifolium*, *Cotoneaster integerrima*, or *Hippocratea comosa*. In Slovakia it grows mostly in the relic plant communities of rock crevices, ravines, and scree (alliance *Seslerio-Festucion duriusculae* KLIKA 1943), in the soam of communities of thermophilous oak forests (alliance *Geranion sanguinei* TH.-MÜLLER 1962) and in mountain meadows (alliance *Calamagrostion variae* SILLINGER 1931, *Poion alpinae* OBERDORFER 1950 etc.). In the meadows of the White Carpathians (Bílé Karpaty) it grows in the alliance

Danthonio-Stipion SOÓ 1947. The geological ground of localities is formed mainly by limestone, dolomite, Carpathian sandstone and volcanic rocks, more rarely this taxon occurs on crystalline rocks. The nomenclature of the polyploid complex of *Leucanthemum maximum* (RAM.) DC. has not yet been solved; I am using therefore the provisional name.

Die 21. V. 1959

Leg. A. Chrtková-Žertová

Lotus corniculatus L. is a very variable species characterized by a wide ecological amplitude and a very large distribution area. Var. *corniculatus* belongs to a group of varieties which appear to be an intricate hybridogenous complex within the tetraploid species. It belongs to the most common varieties. It is widespread here and there within the whole distribution area of the species, occasionally it occurs secondarily even in the northernmost parts of the area. It appears to be most frequent in Central Europe where it splits in a number of forms and ecomorphoses. The chromosome number $2n=24$.

Die 19. VII. 1962

Leg. J. Ujčík

O. tornensis is a local endemic species on the territory of the Slovakian Karst; it occurs only on 3—4 localities near the town of Turna n. Bodvou, in the vicinity of the Czechoslovak-Hungarian frontier. This species belongs to the section *Stelligera* SCHUR Enum. Pl. Transsilv., 468, 1866, restr. HOLUB hoc loco (restrictio sensu *Onosma* L. sectio *Asterotricha* BOISS. Fl. Orient. 4:180, 1879; typus *O. stellulata* WALDST. et KIT.), and here to the series *Stellulata* (M. POPOV) HOLUB, comb. nova (basionym: *Onosma* L. sect. *Euonosma* CLARKE subsectio *Asterotricha* (BOISS.) M. POPOV grex *Stellulata* M. POPOV Bot. Mater., Leningrad, 14:303, 1951). It is a diploid species with $2n=14$ (found in the material from the locus classicus where our specimens were also collected). As regards its habitat, *O. tornensis* is bound to limestone slopes with the karst type of disintegration, grown over with xerophilous phytocoenoses of the order *Festucetalia valesiaceae* BR.-BL. et TX. 1943 which form the stands in the clearings of forest-steppe communities of the sub-alliance *Eu-Quercion pubescentis* KLIKA 1957 and of the alliance *Prunion fruticosae* TX. 1952.

Die 10. IX. 1936

Leg. J. Černý

The given locality is the only one known in Czechoslovakia. It was discovered for the first time by J. ČERNÝ in 1932; the find was subsequently published by DOMIN (1936). This mediterranean plant, however, is not native here, it was undoubtedly brought in by chance: it inhabits only fallows, whereas in the original plant communities in the environs of the locality it does not occur. DOMIN (1936) regarded this plant erroneously an *P. cephalotes*, not only because both species are morphologically very alike, but evidently also because *P. cephalotes* penetrates most northwards of all species of the genus (up to N. Hungary, not far from the Slovakian frontier). *P. kapela* differs from *P. cephalotes* first of all by distinctly smaller flowers. The flowers of our plants are up to 2.5 mm long. CHAUDHRI (1968) gives for *P. cephalotes* the flower length (2.5) 3—4 (4.5) mm. Some flowers of our plants possess the sepals of different length and approach in this respect to *P. capitata* (L.) LAM. This species also differs by larger flowers, and its leaf-blades, as a rule, are pubescent.

Moravia austro-orientalis, distr. Uherské Hradiště, montes Bílé Karpaty: in nemore lucido Lipiny dicto inter vicos Nivnice et Korytná, c. 250 m s. m.

Die 27. VIII. 1933

Leg. F. Weber

These specimens of *Peucedanum carvifolia* originate from the only locality of this species in Moravia. In Slovakia *P. carvifolia* is distributed mainly in the southern parts of the country, first of all in the floristic region "Matricum", and locally it is rather copious there. The occurrence of the species in Bohemia was reported more recently from Hluboš near Příbram (CHRTEK et HENDRYCH Acta Univ. Carol. Biol., Praha, 1962:146, 1962), based on the finding of an old herbarium sheet dating back to the beginning of the 19th century. The natural occurrence of this representative of submediterranean floristic element in the Hercynian floristic region is, from the phytogeographical standpoint hardly probable; they are most likely cultivated plants from the garden of the local mansion. As result of drying or age of the material, some of our plants possess whitish petals, which is a characteristic feature of the closely related species *P. schottianum* DC. and is also alleged to be a character of the problematic taxon *P. euphymiae* KOTOV described from the Ukraine; but if studied in the same locality, the plants show a distinctly yellowish-green coloration of petals which is characteristic of *P. carvifolia*.

The nomenclature of this species is rather intricate and extensive due mainly to its being placed in various genera sometimes based on this species (*Caroselinum*, *Schlosseria*, *Pteroselinum*) as well as to a certain

infraspecific differentiation. The problems connected with the question of the correct name of the edited *Peucedanum* species were for the most part solved by THELLUNG in HEGI III. Fl. Mittel-Europa 5/2:1375, 1926. The question of the generic classification of the species under discussion has not yet been fully solved and is dependent on the monographical revision of the genus *Peucedanum*.

Die 5. VI. 1962

Leg. J. Soják

P. lindackeri belongs to the interesting group *Collinae* WOLF which includes stabilized hybridogeneous species arisen by crossing of various species belonging to the sections *Aureae* and *Argenteae*. In the group *Collinae* *P. lindackeri* is numbered among the species with a slightly developed tomentum beneath the leaflets. This group of species was

included by ASCHERSON and GRAEBNER (1904) into an artificial collective species *P. theodoriana* ASCH. GRAEBN. The morphological differences among individual taxa of the group "Theodoriana" are often very minute, but their diacritical features are relatively constant, and the individual taxa have distribution areas of their own, which are often detached each from other by extensive disjunctions; thus it may be assumed that they arose in particular regions independently. For this reason they are to be regarded as independent species. *P. praecox* F. SCHULTZ (Switzerland) differs from *P. lindackeri* by the softer and more spreading indumentum of the whole plant and by larger flowers, *P. alpicola* DE LA SOIE (Western and Southern Alps) by the ground leaves which are withered at the blooming period, being mostly pentamerous, *P. porphyracea* SAUTER (Tyrol) by the longer pubescence of petioles and often by a different dentation of leaflets, *P. rhenana* P. J. MÜLL. (basin of the Rhine and Moselle) by larger flowers and by leaflets with more elongated teeth and sparse long hairs beneath; *P. thyrsiflora* HÜLS. ex ZIMM. (E. Europe), which was very often confused with *P. lindackeri*, differs from the Bohemian plants by slightly developed long hairs beneath the leaflets (the leaflets are therefore dull beneath), by a better developed tomentum, by larger flowers and by other characters. *P. lindackeri* grows in Central Bohemia, first of all on the terraces of the river Vltava and its tributaries. The centre of the distribution area extends from the town of Příbram to the northern environs of Prague. Outside Bohemia it occurs in one locality only, i. e. in the environs of the town of Coswig in Saxony. *P. lindackeri* is a variable species with a fluctuating intensity of indumentum on the upper and especially lower side of leaves, with a variable number of teeth on leaflets and with both heptamerous and pentamerous leaves. That was the main reason why some individuals of *P. lindackeri* were determined as *P. thyrsiflora*, others as *P. leucopolitana* P. J. MÜLL., and others again were separated as *P. opizii* DOM.

Die 21. VII. 1930

Leg. I. Klášterský

Rosa bellavallis PUG. was edited as exsiccate already once, many years ago, under the synonym *Rosa Kmetiana* BORB. (Fl. exsicc. Austro-Hung. no. 857, 1883 — legit A. KMETÍ), from the same area as my material was collected. R. KELLER (1926) subjoined *R. kmetiana* to the species *R. subcollina* HAYEK as a variety; the taxon, however, bears all characters of *R. coriifolia* FRIES, especially the sepals are fully erected, and therefore it does not belong to the *R. subcollina* complex. It is widespread almost everywhere within the distribution area of *R. coriifolia*, but its occurrence is much less frequent. It arose by the introgression of some glandular species into the population of *R. coriifolia*, so that its origin is probably polytopic; nevertheless, the differences concern only the less substantial characters, and the preservation of the taxon as a species within the *R. coriifolia* complex is legitimate. $2n = 35$ (I. KLÁŠTERSKÁ 1967).

I. KLÁŠTERSKÝ

Rosa canina L.
var. **dumalis** BAKER

in Journ. Linn. Soc. 9:277, 1869.

Bohemia centralis, distr. Praha-západ: in valle Radotínské údolí prope oppidum Radotín, in declivi septentrionali ad marginem silvae (Querco-Carpinetum), solo calcareo, c. 280 m s. m.

Die 23. VI. 1933

Leg. I. Klášterský

The species is widespread all over the territory of Czechoslovakia as the commonest representative of the genus; it grows from the lowlands to the boundary of the subalpine belt; at high altitudes it often does not flower at all. Var. *dumalis* BAKER (with the leaflet edge doubly to compoundly serrate) is much more frequent than var. *lutetiana* (LÉM.) BAKER (where the leaflet edge is simply serrate) which represents a purer and more original form of the species, but which is also influenced by introgression to such a degree that the individuals of the typical habitus are rather rarely to be found.

Die 5. VIII. 1932

Leg. I. Klášterský

The species belongs to the complex of *Rosa agrestis* SAVI, from which it differs by petioles, rhachis and leaflets which are densely pubescent at least beneath (but often even above), and by stalky-glandular pedicels. Erection or irregular position of sepals can sometimes be observed in this species, as is known, e. g., in *R. inodora* FRIES within the complex. *R. gizellae* is most closely related to *R. albiflora* OPIZ (1822). These species are both distributed rather copiously in Central Europe being more frequent towards the East; the eastern boundary of their distribution is not known. In Czechoslovakia both species occur comparatively frequent in lowlands, hills and in the lower montane belt. Like all species belonging to the *R. agrestis* group, this species has $2n = 42$ and an irregular meiosis (I. KLÁŠTERSKÁ 1969, manuscr.).

Die 22. VII. 1930

Leg. I. Klášterský

The species is distributed in the mountains of Central Europe, especially in the Alps, but it penetrates to the Pyrenees, the Apennines, and on the Balcan Peninsula up to N. Albania. In Czechoslovakia it occurs only in the West Carpathians, but only a few scanty localities are known there. In some morphological characters this species seems to be related to the section *Cinnamomeae* CRÉP. where I placed it (KLÁŠTERSKÝ in Flora Europaea 2:27, 1968). However, cytological analysis (I. KLÁŠTERSKÁ, 1969 : $2n = 28$, irregular meiosis) has shown that this species belongs undoubtedly to the section *Caninae* DC., although it occupies a special position within this complex (subsection *Rubrifoliae* CRÉP.). The present specimens belong to var. *glauca* f. *laevis* SERINGE in DC. Prodr. Syst. Natur. 2:609, 1825.

Die 19. VII. 1930

Leg. I. Klášterský

The hybrids of both species inhabiting in Czechoslovakia frequently the same localities in the Carpathian region, were found there several times in comparatively different forms. The population on the Tanád Mt. has been known for more than 100 years and is still very viable. The plants correspond very well with KITAIBEL'S description and with the figure of the finding from Mátra (Hungary); they are different in less substantial characters only, and that is why I have used KITAIBEL'S denomination — *R. reversa*.

In 1950 *R. reversa* was transferred into the rosarium at Průhonice, where four individuals are now cultivated; they are 120—140 cm high, they flower copiously and fructify well (the ripened elipsoidal hips are black), their seeds are viable. $2n = 28$ [I. KLÁŠTERSKÁ 1969]. Only a small number of seeds is obtained by autogamy, its experimental crossing with *R. pendulina* L. and *R. majalis* HERRM. was successful [D. JIČÍNSKÁ 1967].

Die 4. VIII. 1932

Leg. I. Klášterský

This species is widespread all over the territory of Czechoslovakia, from lowlands up to the higher hills, under very favourable conditions up to the lower mountain belt. It grows on all substrata (except in moist areas), but it grows distinctly more frequently on limestones and dolomites. The variability of morphological characters within narrow limits is sizable, but from the taxonomical viewpoint unimportant. Especially the dividing into heteracanthous and homoacanthous forms is of a very dubious value, because the young individuals are predominantly homoacanthous, but later on become heteroacanthous, especially if they grow under optimum conditions. Not infrequently suprafoliar glands appear (usually irregular, on some leaves only and not very numerous). In some habitats in the Carpathian region of the Czechoslovak territory, however, the suprafoliar glands are developed on all leaves in many individuals and so numerously, that by this character (but not by the others!) they resemble the species *R. caryophyllacea* BESS., which rarely occurs in this area.

Die 15. VIII. 1938

Leg. J. Suza

The centre of the distribution area of this species is situated in Western Europe, into Central Europe it penetrates only rarely. In Czechoslovakia the number of finding places decreases rapidly from West to East. *T. scorodonia* occurs in the western half of Bohemia, in single cases it penetrates into Moravia and Silesia (in total, about 5 localities are known), in Slovakia it has been found in one area only, viz. in the Tribeč Mts. in the West Carpathians (where our plants were collected). According to SUZA (1939) who investigated in detail the plant association in which *T. scorodonia* in Slovakia occurs, this occurrence is original. It represents an important enclave advanced far eastwards off the continuous distribution area of the species. On the contrary, DOSTÁL (1949) assumes that this species in Czechoslovakia is native in West Bohemia only, all other plants he regards as naturalized. It is difficult to decide if *T. scorodonia* in Slovakia is native or not; however, the author supposes that the autochthonous occurrence of this species in the Tribeč Mts. is not impossible.

The species — widespread from the Spanish mountain ranges to Yugoslavia (northwards up to N. Moravia) — is represented in Czechoslovakia only by the East Alpine — Carpathian race, ssp. *austriaca* WALTHER. This race is characterized by smaller flowers, glabrous or only sparsely hairy leaf blades which are only shortly fringed at the edges. In Czechoslovakia it occurs in northern Moravia (Jeseníky Mts. and Beskydy Mts.), in Slovakia it is distributed all over the Carpathians.

Die 4. VI. 1965 (flor.)

Leg. A. Chrtková-Žertová

A submediterranean species distributed in S. and S. E. Europe. By an isolated exclave pushed considerably northwards it penetrates into the territory of N. W. Slovakia where it was found only several years ago (ŽERTOVÁ 1962). It occurs here in a few localities in the southern part of the Little Carpathians (Malé Karpaty). It grows in the forest-steppe communities on the slopes facing the south and southeast at altitudes of about 300 m a. s. l. The nearest finding place is in Austria, as far as in the S. E. promontory of the Alps. *V. incana* belongs to the section *Cracca* S. F. GRAY. It belongs to the more ancient and more stabilized diploid species with less variability. The chromosome number is $2n = 12$ (ŽERTOVÁ 1963). The most related species is the polymorphic *V. cracca* L. The two species differ in the indumentum of stem, in the number of leaflet pairs, by the shape of calyx-lobes and petals, in the shape of fruits and in the size of seeds.

Die 23. VII. 1967

Leg. J. Holub et J. Měsíček

Zerna ramosa is easily distinguished from the closely related species *Z. benekenii* (LANGE) LINDM. mainly by the indumentum of the sheath of the uppermost leaf (with long ± spreading hairs), by the structure and size of the panicle (panicle effuse, widely pendent, 15—35 cm long, loose even when ripened) and by other morphological characters; from the viewpoint of biology, it is distinguished by its rather different phenology (it comes into flowering 2—4 weeks later than *Z. benekenii*). In Czechoslovakia *Z. ramosa* is much less frequent than *Z. benekenii* and confined to certain areas only; the general distribution of *Z. ramosa* is also smaller and bears to some extent the sub-oceanic character.
